ABERRATIONS

The two sections of this article give a theoretical treatment. For an introductory discussion, see the article entitled LENS.

Geometrical Theory. When a light wave passes through an instrument, the wave front suffers deformations due to the imperfection of the instrument. The optical distance between the emerging wave front and the converging wave front, when the mapping of object points is perfect, is a measure of the aberration of the instrument. It is a function of position of the intersection of the rays with the actual wave front and those with the ideal wave front (perfect mapping). This function is called the *aberration function*. For rotational optical systems, it depends on three invariants, and when the aberration is small, it is expanded in a power series in these invariants. In the following section, we have given the expansion in two different forms, known as the standard and the Zernike-Nijboer expansions and briefly discussed the classification of the terms according to the powers of the invariants. For the analysis of geometrical aberrations and the classification of various types of aberrations, we refer the reader to the references listed in the section below and to the following comprehensive treatise on the subject: Herzberger, M., "Modern Geometrical Optics," New York, Interscience Publishers, 1958.

Diffraction Theory. The starting point of the modern theory of diffraction of optical instruments may be traced to the famous paper on diffraction theory of the phase contrast method by Zernike.¹ The extension to the diffraction theory of aberrations was carried out by him in collaboration with his pupils, especially, Nijboer.² Since then, many advances have taken place, both in theory and experimental observation leading to important applications in the improvement of optical instruments. However, prior to Zernike's pioneering work, some significant contributions to the theory were made by a number of authorities, notably Inगतowski, Fischer, Steward,³ and Picht.⁴

The basis of the diffraction theory of optical instruments is founded on Kirchhoff's integral or a modified form of it, namely

$$U(P) = \frac{ikn}{2\pi} \iint_S \sqrt{KU_0(Q)} \exp ik[W + (\mathbf{r} \cdot \mathbf{s})] dS \quad (1)$$

where $U_0(Q)$ is the value of the field on the wave surface (front) S , K and \mathbf{s} are respectively the gaussian curvature and optical normal vector of S , n is the refractive index of the medium in the image space, and W is the Hamiltonian mixed characteristic of the optical system. The image field $U(P)$ at an image point $P(x, y, z)$ is the geometrical optics wave solution of the scalar wave equation, or Maxwell equations.

A more convenient form of Eq.(1) used frequently in actual problems is

$$U(P) = \frac{ik}{2\pi} \iint_{p^2 + q^2 \leq n^2} g(p, q) \exp ik\phi(P; p, q) dp dq, \\ \phi(P; p, q) = W + (\mathbf{r} \cdot \mathbf{s}) \quad (2)$$

where a point Q on the wave surface $S(Q)$ is represented parametrically in terms of (p, q) , $x = -W_p + \lambda p$, $y = -W_q + \lambda q$, $z = \lambda \sqrt{n^2 - p^2 - q^2}$, $\lambda = \lambda(p, q)$. Here p, q and $(n^2 - p^2 - q^2)^{1/2}$ are the optical direction cosines (components) of the normal vector \mathbf{s} . The amplitude function $g(p, q) = |n| |\Delta|^{1/2} U_0(p, q)$ remains constant along a ray (p, q) in image space, and Δ is the discriminant of the second differential form of S . Equations (1) or (2) are known as the Picht-Luneberg integrals.^{1,5}

The above formulas give all the information about the image produced by an optical instrument for a monochromatic source. Thus the problem is reduced to the evaluation of such integrals over the arbitrary wave front S . In general, W is not known explicitly (closed form) on S , so instead of the wave surface S one takes a reference surface S_0 , usually a spherical wave front with center at the gaussian image point of the optical system, and expands W in a Taylor series in the parameters. In practice S_0 is the aperture (entrance or exit-pupil) of the instrument. For rotational symmetric systems, most frequently employed in practice, W depends on three invariants, $u_1 = x_0^2 + y_0^2$, $u_2 = p^2 + q^2$, $u_3 = x_0 p + y_0 q$, and an additional invariant $u_4 = x_0 q - y_0 p$ for electron optical systems. Therefore, the expansion of W is of the form

$$W = W_0 + \sum a_{1i} u_i + \sum a_{2ij} u_i u_j + \sum a_{3ijk} u_i u_j u_k + \dots, \\ (i, j, k = 1, 2, 3),$$

$$= W_0 + \sum_{p=1}^{\infty} \sum_{n=1}^{\infty} \sum_{m=1}^n b_{lnm} \sigma^{2l+m} \rho^n \cos^m \phi =$$

$$W_0 + \sum_{n=1}^{\infty} \sum_{m=0}^n f_{nm}(\sigma) \rho^n \cos^m \phi \quad (3)$$

l, n, m are positive integers, $n - m$ even ≥ 0 and $u_1 = \sigma^2$, $u_2 = \rho^2$, $u_3 = \sigma \rho \cos \phi$. The individual constants b_{lnm} are the aberration coefficients. This standard development has been used by Steward and others in their treatment of diffraction of aberrations. However, even for individual aberrations of lower order, the evaluation of the diffraction integral leads to complicated expressions for the image field or intensity distribution, since the various orders of a single type aberration are not separated; consequently, it is difficult to separate the contributions of each order to the total intensity in the image plane. For these reasons, both Steward and Picht and later Born obtained incomplete figures of the intensity distributions of the image. On the other hand, Nijboer, following Zernike's ideas, was able to calculate to a great degree of accuracy (unknown before) the intensity distribution for several types of aberrations and high orders. The experimental observations made at Zernike's laboratory, as well as those made at McGill University on microwaves^{2a} are in agreement with Nijboer's figures or with those calculated by Nijboer's method.^{2a}

The Zernike-Nijboer diffraction theory of aberration is based on the development of the aberration function, or W , in terms of orthogonal polynomials (functions) over the region of integration (wave front) which, in their case, was a circle. Instead of Eq. (3), W is expanded in the form

$$W = W_0 + \sum_{n=1}^{\infty} \sum_{m=0}^n f_{nm}(\sigma) Z_n^m(\rho) \cos m\phi,$$

$$(m = 0, 1, \dots, n; n = 1, 2, \dots) \quad (4)$$

where $Z_n^m(\rho)$ are called the Zernike polynomials, which are orthogonal over a unit circle. In this development, a typical aberration term is of the form $b_{lnm} \sigma^{2l+m} Z_n^m(\rho) \cos m\phi$. On account of the orthogonality of Z_n^m , the various orders of a single aberration enter individually (are not mixed) in the expression representing the intensity distribution function; i.e., different aberrations cannot counterbalance each other's contribution for all σ . In general, the amplitude function can also be expanded in Zernike polynomials, or other functions such as Fourier-Bessel, or Dini functions,¹⁰ if the field over the aperture is not constant (coating of lenses). In general, the idea of expanding both the amplitude and the phase function in orthogonal functions over the domain of integration has many advantages over previous methods, since the double integral cannot be reduced into a single integral, except for the simplest type of apertures. However, when only spherical aberration of all orders is considered, the method of integration by parts of the diffraction integral leads to rather simple expression for

the image field. This case has been treated exhaustively for both circular and annular apertures by Boivin.⁸

All the methods discussed above are valid only for small aberrations. For large or moderately large aberrations, one must resort to asymptotic methods, which at present are sufficiently developed to include most of the interesting cases occurring in the theory of diffraction of optical systems. When these analytical methods are combined with the present progress in computational methods, the intensity distribution produced by an optical system can be calculated to any desired degree of accuracy.

ABSORPTION SPECTRA

The first experiment in which the light from the sun was dispersed into its spectrum was performed by Sir Isaac Newton in 1666. The chief effect was, obviously, the transformation of the round pin-hole image of the sun in white light into a sausage-shaped array of colors, starting with red and ending, further up the wall, with violet. There was only a gradual transition from one color to the next, and apparently no colors were missing between violet and red.

The next step in the new optical topic of spectroscopy was the observation by W. H. Wollaston (1766–1828) in 1802 that the solar spectrum is not complete, but is crossed by a large number of dark lines—apparently missing wavelengths. A dozen years later Joseph von Fraunhofer (1787–1826) again observed these dark lines in the solar spectrum. In 1859 they were explained by Kirchhoff as due to the fact that the elements which, when in the laboratory, give characteristic bright lines in their spectrum, would in the solar atmosphere absorb those very lines—hence relative darkness is apparent at these places in the spectra when viewed from the earth.

Distinctions should be made at this point between several terms used in the discussion of absorption spectroscopy.

The *absorption coefficient* of a material (α) is expressed in the equation, known as the law of absorption and enunciated by Bouguer and Lambert,*

$$I_x = I_0 e^{-\alpha x}$$

in which the intensity of an incident plane wave I_0 is shown to decrease as the reciprocal of an exponential function to a value I_x after the energy has penetrated to a distance x in the sample of the material. In other words, the fraction dI/I_0 of the initial intensity is "lost" in traversing the distance dx , since $dI/I_0 = -\alpha dx$.

Absorption is the general phenomenon taking place within the body of the material as measured by the absorption coefficient.

Absorbance is the common logarithm of the ratio of the incident to the transmitted intensities.

Absorptance is the measure of the amount of light that disappears at a single reflection.

No substance has been found to exist that does not strongly absorb some wavelengths if the range be sufficiently extended. Dielectrics usually exhibit three extensive regions of large transmission, one in each of the three distinctive portions of the electromagnetic spectrum—very short wavelengths, intermediate wavelengths, and very long wavelengths.

A *blackbody* absorbs all of the radiant energy incident upon it— is a perfect absorber—and likewise acts as a perfect radiator. Kirchhoff's law of radiation states that the ratio of the *emissive power* to the *absorptive power* is the same for all bodies at a specified absolute temperature, or $E/A = \text{a constant} = E_{\text{B}}$. E is the total energy radiated per square centimeter of surface per second and A , the *absorptive power*, is the fraction

* Pierre Bouguer (1698–1758) and Johann Lambert (1728–1777). It was later shown by Beer that the absorption coefficient for a solution is directly proportional to the concentration of the absorbing species. The relationship, known today as Beer's law, is

$$I = I_0 10^{-abc}$$

where a is the *absorptivity*, b is the thickness through which the initial intensity I_0 drops to I , and c is the concentration of the absorbing material.

of the incident energy that is not reflected or transmitted by the surface. Obviously, A is unity for a blackbody, and hence the constant in the above equation is E_{B} , the emissive power of a blackbody at the specified temperature. Absorption lines in a spectrum can be explained on the assumption of *RESONANCE* of the atoms of the absorbing material to that portion of the incident energy spectrum which presents the same oscillation frequency. The atoms reradiate all of the absorbed energy *but in all directions*, so that the portion in the line of sight of the observer is relatively less than what would have been in that position without the intervening vapor.

A material that reduces the intensity of incident light almost entirely without regard to wavelength is said to exhibit *general absorption*. White light becomes gray. In the instances cited in this article, there is *selective absorption*. Flowers, paints, skin, etc., have color by selective absorption since some of the light penetrates ever so slightly into the body of the material.

The absorption bands in the spectra of solids and liquids are usually continuous, gradually fading out along the wavelength axis, but gases show narrow lines in their absorption spectra as a general rule.

We know from elementary optics that the *index of refraction* (n) of a nonconducting material (dielectric) at a definite wavelength is its essential property, for by its use in Snell's law, we can obtain the sequence of deviations of a ray as it passes through or from an interface bounding two media (see REFRACTION). The case is very different for metals (conductors) due to the presence of free electrons in among the atoms. Strong absorption at once occurs so that metals are opaque, certainly to visible light. When the optical properties of metals are being considered, it is more efficacious to use the quantity known as the *absorption index*, defined for a given wavelength λ by

$$\kappa = \frac{\alpha \lambda}{4\pi n}$$

where n is best determined by the measurement of Brewster's angle. (see POLARIZED LIGHT). For silver at $\lambda = 589.3\text{m}\mu$, $n = 0.177$ and $\kappa = 20.554$.

The theory of dispersion shows that generally, in the visible region, transparent materials exhibit a decrease in refractive index with wavelength (section AB of Fig. 1). This part of the graph (AB) is known as the *normal dispersion curve* for the material and can readily be plotted from data taken with a prism spectrometer. The earliest attempt to relate n to λ was made by Cauchy in 1836, namely,

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4}$$

where A , B and C are constants. Although based, as we now know it, on false assumptions, this relationship has proved valuable as a practical working equation, as long as one keeps far from an absorption band. Considering the effect of the

FIG. 1. Index of refraction vs. wavelength for a typical material. Adapted from Fig. 23D of *Fundamentals of Physical Optics*, by Francis A. Jenkins and Harvey E. White, courtesy of McGraw-Hill Book Co., New York, 3rd Edition, 1957.

frequency of the incident light (ν) upon the particles of the medium, having a natural frequency ν_0 , Sellmeier (1871) derived the more acceptable relation

$$n^2 = 1 + \frac{A\lambda^2}{\lambda^2 - \lambda_0^2}$$

where A is a constant proportional to the number of oscillators affected and λ_0 is the wavelength corresponding to ν_0 in a vacuum. We see from this equation that at resonance (when $\nu = \nu_0$), the index of refraction becomes very large. In the event that there are many possible natural frequencies, the Sellmeier equation can be generalized to

$$n^2 = 1 + \sum_i \frac{A_i \lambda^2}{\lambda^2 - \lambda_{0i}^2}$$

A very familiar illustration of absorption is the traffic signal. Even the layman realizes that the practically white light of the high wattage incandescent lamp inside the bowl is *modified* by the presence of the colored material through which the light reaches his eyes. What colors he does *not* see, he assumes are "absorbed." The following experiment may serve to clarify this point.

Let a beam of white light fall upon a flat slab of some dyed material and assume that we are able to measure wavelength by wavelength the percentage of the reflected energy (reflectance R), the percentage of the absorbed energy (absorbance A) and the percentage of the transmitted energy (transmittance T). Because of the law of conservation of energy, it is evident that

$$\begin{aligned} &\text{REFLECTANCE} + \text{ABSORPTANCE} \\ &+ \text{TRANSMITTANCE} = 100 (\%) \end{aligned}$$

(See Fig. 2.)

If the particular values of these characteristic factors are read off at, say, $600 \text{ m}\mu$, it is seen that about 4 per cent is reflected, 31 per cent is absorbed (turned into heat), and the remainder, 65 per cent, is transmitted. The material is said to exhibit *selective* reflectance, absorbance and transmittance, since not all wavelengths are equally affected. In fact, it is observed from the

curves that the slab is probably somewhat reddish by reflected light and amber by transmitted light. No light at all is passed below about $520 \text{ m}\mu$.*

FIG. 2. Distribution of energy vs. wavelength for a slab of dyed material.

The situation would be somewhat different if the sample of material was a thin film of a normally colorless material, such as glass, gelatin, cellophane or acetate, which has been colored by means of a dye—as in the case of a filter. The first surface of the vehicle will not exhibit any selective reflection and the energy distribution will be that of the light source. (It should be observed, however, that the *amount of energy reflected* will depend upon the *angle of incidence*, in accord with Fresnel's reflection formulas.) The dyed material will show selective absorption and transmission. The transmittance curve for a certain blue filter, obtained with a spectrophotometer, is given in Fig. 3. Note should be made of the broad absorption band between about 550 and $630 \text{ m}\mu$. Still more striking is the spectrophotometric curve for didymium (Fig. 4), a material shown originally by von Welsbach to be a mixture of two rare earth elements, praseodymium and neodymium, each of which in solution exhibits intense absorption spectra. To the eye, a didymium filter appears to be pale pink. The range of absorption becomes sharper as the temperature approaches that of liquid air.

Absorption in the visible region (400 to $700 \text{ m}\mu$) has been illustrated by the transmittance curve of the blue filter (Fig. 3) and may be quite graphically understood by the behavior of many dyes in the solid state. As an example, fuchsin exhibits strong absorption in the green region of the spectrum and at the same time reflects a brilliant green. As an absorption band is approached during the determination of dispersion data (Fig. 1), the

* The hue ranges in the visible spectrum are ($\text{m}\mu$): violet, 400 – 450 ; blue, 450 – 500 ; green, 500 – 570 ; yellow, 570 – 590 ; orange, 590 – 610 , and red, 610 – 700 .

FIG. 3. Transmittance curve for a typical blue filter.

index of refraction is found to change rapidly as the band is entered; in fact, measurements become very difficult if not impossible. Reflection is greater in this region than elsewhere. The matter is summed up in the first diagram (Fig. 1) indicating that the *normal dispersion* curve for the material extends from A to B, where the Cauchy equation holds quite well, but behaving in a peculiar manner at some point C where the Cauchy equation will not give the observed effects. Once the absorption band is passed, as indicated

FIG. 4. Transmittance of a didymium filter.

by the two vertical dashed lines, in this case in the infrared, Cauchy's equation, with new constants, begins again to apply, A'B' corresponding to AB. Absorption bands can be observed for hydrogen chloride in the infrared and for ammonia in the microwave region.

X-ray absorption spectra form a very important part of the subject of absorption. Essentially the procedure is to direct a narrow beam of x-rays upon a sample of the material (of thickness x), and then allow the modified beam to impinge upon the atom planes of a crystal of known spacing (d). The diffracted x-rays come out of the crystal at such angles θ as to satisfy Bragg's law

$$n\lambda = 2d \sin \theta$$

and are received by a detector. The latter may be an ionization chamber or a photographic plate. Each setting of the x-ray spectrometer corresponds to a definite wavelength. The values of the intensities measured by the detector with the sample in place (I) and without the sample (I_0) are found from

$$I = I_0 e^{-\mu x}$$

where μ is the absorption coefficient of the material. If we are to take account of scattering and possible fluorescence, then we must write

$$\mu = \sigma + \tau$$

where μ is now the total fraction of the incident energy lost by the beam per unit volume of material, σ is the fraction of the incident energy scattered per unit volume and τ is the fraction transformed into *fluorescent radiation*. If ρ is the density of the material, then the mass absorption coefficient* of the material is

$$\frac{\mu}{\rho} = \frac{\sigma}{\rho} + \frac{\tau}{\rho}$$

and represents the fraction of the energy removed from the incident beam of unit cross section per unit mass. If M is the atomic mass of the isotope of the element being investigated and N_0 is Avogadro's number, then the *atomic absorption coefficient* is defined by

$$\mu_a = \frac{\mu}{\rho} \frac{M}{N_0}$$

As an example, for copper, with x-rays of wavelength 7 mμ, the value of μ_a for copper is 50×10^{-22} cm²/atom. From a study of the variation of μ/ρ with λ , knowledge of the energy levels within an atom has been gained.

Included among the practical uses of absorption spectroscopy as an experimental tool are: (a) to learn which wavelengths of electromagnetic radiation are absorbed, (b) to discover how much of this energy is absorbed under given conditions and then, (c) as a final goal, to find out *why* absorption takes place—and *where*. If we wish to obtain information as to the location and

* Considerable research on mass absorption coefficients has been done by Professor S. J. M. Allen at the University of Cincinnati.

brightness of the absorption lines or bands, a spectroscope or spectrograph is used; if we wish to learn how the energy is distributed throughout the spectral region under investigation, we use a spectrophotometer. Reflectance and transmittance curves are obtained with the latter instrument and a specification of the "color" of the sample in either case can be determined using the C.I.E. methods.

Absorption spectrophotometry is the technique whereby one establishes the relationship between wavelength and radiant energy as the latter proceeds into a given material.

ACCELERATION. See DYNAMICS.

ACCELERATORS, LINEAR

Linear accelerators (often abbreviated to "linacs") are used for acceleration of electrons, protons and heavy ions. Electron linear accelerators have yielded electrons at energies above 1 BeV; proton linear accelerators have not yet reached energies above 70 MeV.

Although the term "linear accelerator" is occasionally used to describe systems in which particles are accelerated by electrostatic fields (Cockcroft-Walton or electrostatic accelerators), the term is generally used to apply to systems in which particles are accelerated along a linear path by application of rf fields. Only accelerators of this type will be discussed in this article.

The linear accelerator has the advantage that the accelerated beam is easily extracted for experimental use. In principle it is capable of producing well-focused beams of higher intensity than are available from circular machines of the synchrotron or synchrocyclotron type. It does, however, require very high power levels at frequencies where conversion equipment is relatively expensive. For a given final energy, a linear accelerator will usually be materially more expensive than a synchrotron. (For a general discussion of accelerators see ACCELERATORS, PARTICLE.)

Field Patterns used in Linear Accelerators. The rf fields used for acceleration are set up in a long cylindrical cavity whose axis is to be the axis of the accelerated beam. Hence for acceleration the field pattern must have a major electric field component parallel to the axis. This requirement is satisfied by the TM_{01} waveguide mode in which a paraxial electric field has its maximum strength at the axis and falls to zero at the cavity wall. Azimuthal magnetic fields lie in planes normal to the axis, have small values near the axis and increase to maximum values at the cavity walls. Usually the field pattern is maintained by coupling to these magnetic fields by loops or apertures excited by external power sources. Corresponding to the high rf magnetic field at the wall, paraxial currents flow in the walls and are responsible for a major fraction of the power loss in the system. When high electric fields are required on the axis to accelerate to high energy in reasonable distances, the wall currents are correspondingly high. For acceleration rates of 2 MeV/m, power losses in copper walls will be of the order of 50 kW/m.

Both standing wave and traveling wave patterns are used in linear accelerators. If traveling waves are used, as is the case in most *electron* machines, the phase velocity of the waves must be made equal to the velocity of the particles accelerated; as the particle velocity increases, the phase velocity also must increase. But phase velocities in simple waveguides always are greater than the velocity of light, and loading must be introduced to reduce the phase velocity to the desired value. This is accomplished by introduction at intervals of washer-shaped irises, as shown in Fig. 1.

Standing wave patterns are used in *proton* linear accelerators. Cavities many meters in length

Fig. 1. Cutaway of iris-loaded waveguide for electron linear accelerator.

are excited in the TM_{010} mode in which the axial field is uniform from one end of the cavity to the other. Protons which enter the cavity at a low injection velocity may arrive at a phase of the rf field at which they are immediately accelerated, but before they have traveled more than a few centimeters, the field will reverse and become decelerating. To protect the particles from the field in its decelerating phase, "drift tubes" are introduced, as shown in Fig. 2. These are pipes

Losses per unit length in waveguides generally decrease as the square root of the rf wavelength for equal axial fields. Hence, where possible, it is desirable to operate at as high a frequency as possible. But, as wavelength is decreased the diameter of the structure and of the beam aperture decrease correspondingly. The highest frequency that gives convenient beam apertures and at which adequate power sources are available is in the 3000-Mc/sec range. For reasons that are pri-

FIG. 2. Cross section through proton linac.

coaxial with the cavity and of such length that the particle is protected from the field during its reverse phase and emerges only after a complete rf cycle when the field again is accelerating. As the particles gain energy, the drift tubes are increased in length.

It would appear that the rather complicated drift-tube structure is conceptually and mechanically inferior to the rather simple iris-loaded traveling-wave system. It is adopted at the relatively low phase velocities required for protons in the range below about 200 MeV because the extreme loading required to reduce the phase velocity of the iris-loaded system to velocities below one-half of the velocity of light results in very high losses. From the point of view of rf power consumption, the drift-tube structure is much superior at low phase velocities.

Electron Linear Accelerators. Electrons very rapidly approach the velocity of light (c) as they are accelerated. At 1 MeV an electron already has reached 94 per cent of its ultimate velocity. At energies higher than this satisfactory acceleration will be achieved if all sections of the accelerator are made to have phase velocities equal to c . This makes much easier the tasks of construction and of operation. For example, rf excitation of a section of the accelerator may fail and the whole machine will still be operative, although at a slightly lower final energy.

marily historic, most electron linear accelerators in the United States are operated at a frequency of 2856 Mc/sec.

Both the phase velocity and the group velocity in the guide are determined by the dimensions of the guide and the loading irises. The group velocity is fixed also by the capabilities of the rf power sources. Klystrons with outputs of the order of 20 MW have become standard; each klystron can excite a section of waveguide 3 meters long to axial fields of 10 MV/m. The group velocity suitable for this operation is 1 per cent of the velocity of light. The dimensions indicated in Fig. 1 result in a phase velocity of c and a group velocity of $0.01c$ when the guide is excited at 2856 Mc/sec.

Injection is from a conventional electron gun. In some cases a short "bunching section" pre-groups the electrons around the peak of the accelerating wave. In this section, the phase velocity is matched to the electron velocity by suitable choices of dimensions.

The power levels required are so high as to preclude continuous operation. Typical operation is with two-microsecond ($2\text{-}\mu\text{ sec}$) pulses repeated several hundred times per second. Of the $2\text{-}\mu\text{ sec}$ pulse, the first half is required to build up the accelerating field.

Electron linear accelerators in the energy range below 100 MeV are widely used for x-ray

production and are commercially available. Most of the pioneer work on electron linear accelerators was done at Stanford where a machine is now (1964) operating at 1.2 BeV and another, two miles long, is under construction and is aimed at eventual operation at 40 BeV. At Orsay, France, a 1.3-BeV electron machine is in operation, and in Kharkov in the U.S.S.R. a 2-BeV accelerator is expected to be in operation during 1964.

Proton Linear Accelerators. Because of the lower velocities of protons at million-electron-volt energies, proton linear accelerators suffer from several limitations from which the electron machines are free. Injectors for protons usually are Cockcroft-Walton voltage multiplier sets giving energies of 500 to 750 keV. At 750 keV the velocity of a proton is only 0.04c. The accelerating field component at such low phase velocities varies strongly with radius at a rate that is approximately proportional to the square of the frequency. This effect sets an upper limit of about 200 Mc/sec for the frequency of the accelerating field, and most proton linear accelerators are operated in the neighborhood of 200 Mc/sec. A cavity resonant in the TM_{010} mode at that frequency will be about 90 cm in diameter.

Figure 2 is a schematic cross section through a 50-MeV proton linac used at the Brookhaven National Laboratory as the injector for the 33-BeV synchrotron. Sections are shown at the injector end, at the region where the protons have an energy of about 10 MeV, and at the high-energy end. The over-all length of the machine is about 33 meters. The drift tube shapes indicated have the purpose of keeping each section of the machine resonant to give a uniform accelerating field pattern and, at the same time, of holding the resistive losses in the walls of the drift tubes to levels as low as possible.

The principle of phase stability is operative in proton linacs whereas, at the extreme relativistic velocities of multi-MeV electrons, electron linacs do not enjoy phase stability and require extreme precision in axial dimensions. In the proton linac, the drift tube lengths increase at a rate corresponding to acceleration at a phase displaced 20 or 30° from the peak of the wave. The phenomenon of phase stability (see ACCELERATORS, PARTICLE) results in continual restoration to the correct phase of protons which enter the machine at phases in the neighborhood of the correct phase. Often prebunchers are used to collect a large fraction of the injected beam around the accelerating phase. These prebunchers have the same design as the modulating gap in a klystron and function in the same fashion.

At the stable phase the field across an accelerating gap is rising as the proton crosses the gap. As the proton enters the gap, the accelerating field has a focusing component, but as it enters the next drift tube it feels a larger defocusing field and the net effect is a strong defocusing. In early proton linacs this effect was overcome by the introduction of rudimentary grids at the downstream end of each gap. These grids give unsatisfactory performance because they intercept a

large fraction of the beam and because their poor optical quality results in loss of many protons. With the advent of alternating gradient focusing, grids in linacs were largely abandoned and focusing is now accomplished by quadrupole magnets imbedded in the drift tubes. This has resulted in an increase in output current by two orders of magnitude to levels of the order of 50 mA.

As in electron machines, the high rf power level required forces operation at a relatively low duty cycle. Since, at this frequency, the time required to build up the field in the linac cavity is about 200 μ sec, pulse lengths for research use are chosen to be several hundred microseconds. Duty cycles are rarely larger than 1 per cent.

The first proton linac was the 40-foot machine at the Lawrence Radiation Laboratory in which protons were accelerated to 32 MeV. Fifty-MeV linacs are used as injectors for the synchrotrons at Brookhaven, Argonne and CERN. The largest linac now in operation is the 70-MeV unit in research service at the University of Minnesota, but a 100-MeV machine is under construction in the U.S.S.R. to serve as the injector for the 70-BeV synchrotron at Serpukhov. At CERN and in the United States, there is, in 1965, much discussion of proton linacs for energies as high as 800 McV for use as synchrotron injectors or as meson research facilities.

Heavy-ion Linear Accelerators. Heavy ions such as C, N, O, Ne and even higher masses can be accelerated in a structure similar to a proton linac but operated at a lower frequency, typically 70 Mc/sec. Multiply charged ions are injected at a few hundred kiloelectron volts and are accelerated to about 1 MeV/nucleon. They then pass through a "stripper," a gas jet in which their charge-to-mass ratio is doubled. The accelerating field now can be twice as effective, and the ions enter a second cavity in which they are accelerated to about 10 MeV/nucleon.

Heavy ion linacs are used in research in nuclear physics and nuclear chemistry and have been particularly useful in the production of transuranium elements.

ACCELERATORS, PARTICLE

The primary purpose of particle accelerators is to serve as artificial sources of well-defined beams of radiation for studies in nuclear science. Not only are the intensities much greater than those provided by cosmic rays, but the energies and directions of motion of the particles are known to high precision. In addition, several types of accelerators are useful for providing x-rays and beams of neutrons for medical applications. Industrial uses include the production of radioactive-tracer materials and beams for sterilization processes.

The basic components of an accelerator consist of a source of particles, an evacuated chamber to keep them from being scattered by air molecules, and a means of providing them with kinetic energy. Acceleration is always accomplished by means of an electric field since mechanical forces or gravitational fields are too weak and magnetic fields only produce a change in direction of the particles. The various types of particle accelerators merely reflect the different methods of applying the electric fields. Only charged particles can be accelerated, but these may include electrons, protons, deuterons, or heavier ions such as multiply-ionized carbon, nitrogen, etc. Beams of neutrons are obtained by bombarding suitable targets (D, Li, Be, etc.) usually with deuterons.

The simplest type of electric field is provided by applying the required amount of voltage between two terminals. About one-half of all existing accelerators are of this DC (direct potential drop) type, but their energies are limited to a few million electron volts.*

The methods by which this direct voltage may be obtained are of two basic types: (1) by means of a cascade process such as the cascade rectifiers or voltage-multiplying circuits and (2) by charging up a terminal through actual transportation of charge.

The *Cockcroft-Walton accelerator* belongs to the former type and consists of several stages of a voltage-doubling circuit together with an ion source and a suitably designed discharge tube. Although it is possible to use electrons, these accelerators are usually used as positive-ion sources and can provide dc currents up to about 10 mA and energies up to about 1.5 MeV without special pressure tanks.

The second method is employed in the *electrostatic*, or *Van de Graaff*, generator where a row or corona points sprays charge onto a moving belt that carries the charge to the field-free region inside a spherical metal terminal. Currents of about 1 mA for electrons, and up to about 500 μ A for positive ions, are obtained in the range 1 to 5 MeV with a precision of about 0.1 per cent. The

whole apparatus is enclosed in a pressure tank and operated at about 10 atmospheres. In this form, the maximum energy is close to 10 MeV and is limited by breakdown between the terminal and its surroundings. However, double the energy can be attained by accelerating negative ions to the positively charged terminal; then, through electron-stripping, positive ions are created which can be accelerated again as they pass from the terminal to ground. Such "tandem" Van de Graaff generators, in two- and three-stage variations, can provide particles in the 10 to 30 MeV range, with high precision.

An electric field may also be produced by a time-varying magnetic field and such a semidirect method of application is used in a *betatron*. The changing magnetic flux in the central core of a pulsed cylindrical electromagnet induces a transverse electric field that accelerates the particles. These travel in a doughnut-shaped vacuum chamber located between the poles of the magnet surrounding the core. The magnetic field between these poles keeps the particles traveling in a circle, but it must be carefully designed to keep the particle orbits within the vacuum chamber during each pulse. Although betatrons can accelerate positively charged particles, they have been used exclusively for electrons. The electrons can be extracted, but they usually bombard an inner target to produce beams of x-rays which can be as intense as 14000 R/min at a distance of 1 meter from the target. Pulsing rates vary from 30 to 60 times per second. The highest energy that has been achieved in a betatron is 300 MeV (University of Illinois), but the majority are designed for the range around 25 MeV. An upper limit to the energy arises from the fact that electrons, when traveling on circular orbits at relativistic velocities, radiate electromagnetic energy. These radiation losses disturb the particles' orbits, and compensation must be provided. This becomes impractical in betatrons above about 300 MeV.

All other types of accelerators use various forms of rf electric fields, at relatively low voltage, which are applied many times in a given direction to the particles and are prevented from influencing them when the rf field is reversed.

One way of applying this principle is used in *linear accelerators* ("linacs") where the particles travel in a straight line down the center of a cylindrical pipe that acts as a waveguide. The waveguide has a rf electromagnetic field pattern whose axial electric-field component provides the accelerating force. To keep the length to a reasonable size, quite high fields (several million volts per meter) are needed with associated high power requirements. This means that the linear accelerator is relatively more costly for a given energy than other accelerators. However, it does have the advantage that a well-focused beam, with small energy spread, can emerge and be readily available for experiments.

The structures of linear accelerators for electrons differ quite markedly from those for protons and heavy ions due to the fact that electrons reach very nearly the speed of light at energies of

* The energy acquired by the particles in an accelerator is expressed in electron volts (eV), the amount of energy gained by any particle bearing a charge equal to that of an electron when it falls through a potential difference of 1 volt. $10^3\text{eV} = 1\text{keV}$; $10^6\text{eV} = 1\text{MeV}$; $10^9\text{eV} = 1\text{GeV}$ (U.S.A.) or 1 GeV (Europe).

a few million electron volts, whereas protons do not reach this velocity until they are accelerated to the billion-electron-volt range. In a *proton linear accelerator*, the waveguide is a resonant cavity where the particles are shielded from a standing rf wave, during the part of the cycle not suitable for acceleration, by a series of "drift tubes," and then are accelerated when traveling across gaps between the drift tubes. As the protons' velocity increases, the drift-tube length increases so that the particles which arrive at a gap at an accelerating phase continue to be accelerated at succeeding gaps. The protons are injected into the linac at energies from 500 to 1000 keV, usually from a Cockcroft-Walton generator. The proton linac is capable of delivering currents of several milliamperes, but usual operation is limited to short pulses (10 to 100 μ sec) with a duty cycle of 1 per cent or less. In principle, there is no limit to the energy, but to date (1965) 70 MeV is the highest achieved, although design studies have been carried out for machines up to 1 BeV. Several proton linacs, of 10 to 50 MeV, are in use as injectors for high-energy synchrotrons. Heavy-ion linacs, similar in design to proton machines, have been built to give energies of about 10 MeV/nucleon.

The waveguide in an *electron linac* is a relatively simple pipe consisting of many small cavities, and the electrons travel in step with the electromagnetic wave. The cavities are coupled by a series of irises (hollow disks) that are constructed to give the proper phase velocity. The whole structure requires extremely close tolerances and strict temperature control. It is usual to use a traveling wave mode of operation although this is not essential. Many electron linacs are in operation up to about 100 MeV, and 1-BeV machines are operating at Stanford University, U.S.A. and at Orsay, France. Average currents up to 1 μ A have been obtained at pulse rates of 60/sec. Under construction, at Stanford, is a 2-mile-long electron linear accelerator for an energy of about 20 BeV in its first stage of operation; then, with the addition of more rf power sources, it will attain about 40 BeV.

Another method of applying relatively small voltages many times to raise the energy of particles is used in the cyclic accelerators. A magnetic field is applied in a direction perpendicular to the particles' plane of motion resulting in a spiraling or circular orbit. Single or multiple rf sources, located on such an orbit, provide increments in energy on each revolution, and the particles continue to circulate until the design energy is attained. In such motion, the magnetic force must balance the centrifugal force, i.e.,

$$mv^2 = evB \quad (1)$$

where e is the charge, m the mass, and v the velocity of the particle, r is the radius of the path, and B is the magnetic flux density.

In a *cyclotron*, the magnetic field is almost uniform over the region between two cylindrical

poles, and it is constant in time. Positive ions originate in an ion source located near the center of the gap and are accelerated across the gaps between two D-shaped electrodes which each cover almost half the area of the magnet poles. Between the "dees" a constant frequency rf field is applied. From Eq. (1), it can be seen that the angular velocity, v/r , of the particle is given by eB/m , that is, it is independent of radius. Thus, the particles always take the same time to cover the distance between the accelerating gaps as they travel on an orbit of half-circles of ever-increasing radius; they arrive at each gap always at the proper phase to continue to be accelerated. The cyclotron is most useful for accelerating protons and deuterons in the energy range between about 5 and 20 MeV, but heavy ions such as multiply ionized carbon, nitrogen, etc., can be accelerated to about 100 MeV. Continuous currents of about 1 mA can be obtained for use with internal targets, or about one-tenth of this can be extracted for external use by means of a deflecting field situated at the outer radius. There is an upper limit in the energy obtainable in a cyclotron because the relativistic increase in mass of the particles as their energy increases causes them to reach the accelerating gap progressively later and to fall out of resonance with the accelerating field. This limit is about 30 MeV for protons and 40 MeV for deuterons.

In the *synchrocyclotron*, this basic limitation is removed by varying the frequency of the accelerating field, decreasing it to keep in step with the decreasing frequency of revolution of the circulating particles. However, even with a wide variation in frequency, the particles can remain at or near the correct acceleration phase. A particle which receives too much energy will travel on a path with a larger radius than the "equilibrium" particle that receives just the right amount, thus the higher-energy one will return to the accelerating gap somewhat later in phase. Phase stability will result if the "equilibrium" phase is on the falling side of the rf wave, i.e., between 90 and 180°. Synchrocyclotrons have been constructed to accelerate positive ions (chiefly protons) to energies from about 100 to 700 MeV, the latter being about the practical maximum due to the size of the magnet. This is similar to that of the cyclotron, the almost constant magnetic field being produced between cylindrical poles. For a 700-MeV design, such a magnet weighs about 7000 tons and the frequency must drop to less than 60 per cent of its initial value. The tuning for the rf systems is provided either by a rotating condenser or a vibrating-reed type of variable capacitor. With such frequency modulation over the accelerating period, it is no longer possible to have continuous acceleration as in the conventional cyclotron. The output of a synchrocyclotron is pulsed and time-average internal currents are only about 1 μ A. Cycling rates vary from 30 to 100 cps.

The *microtron* is a variation of the cyclotron that is used to accelerate electrons. Again, the magnetic field is constant and the accelerating rf field has a constant frequency. The accelerating gap is

now situated at one edge of the magnet, and the circular orbits of the particles are tangent at this point. The amount of energy given to the particles is adjusted so that the time of revolution in each orbit is one or more rf periods longer than in the previous orbit. Thus, the particles return to the accelerating region at the same phase on each turn. Several microtrons have been built for energies from a few million electron volts to almost 30 MeV, with currents of about $1/2 \mu\text{A}$.

The highest energies, for both electrons and protons, have been reached in the *synchrotron*. In this type of accelerator, the particles are kept moving on an orbit that is almost circular, and of a fixed radius, between the poles of a magnet that is annular in shape. For the higher energies, such a magnet is much less costly than the cylindrical synchrocyclotron magnet. From Eq. (1), above, it can be seen that to keep the particles' orbit with a constant radius, the magnetic field must be increased during the period of acceleration from a low value that would correspond to the injection energy to a final value corresponding to the maximum energy. The radius of the accelerator is determined by the value of this maximum energy and the maximum value obtainable for the magnetic field (usually 10 to 15 kilogauss). Accelerating fields are provided by one or more rf stations located at points on the magnet ring, and the frequency must increase exactly in step with the increasing velocity of the particles.

In all cyclic accelerators, focusing forces to keep the particles within the limits of the vacuum chamber are provided by shaping the magnet poles to give a field that varies with radius. Synchrotrons fall into two general categories: (1) weak-focusing, constant-gradient (CG) synchrotrons where a small radial negative gradient has a constant value in azimuth and (2) strong-focusing alternating-gradient (AG) synchrotrons where large radial gradients alternate in sign with azimuth. From the equations of motion of particles in an azimuthally uniform field, the radial field index n [$n = -(dB/dr)(r/B)$] must have values between 0 and 1 for stability in both radial and vertical directions. Stronger gradients provide strong focusing in one plane but result in defocusing in the other plane. Alternating-gradient systems depend upon the principle that a focusing combination can result from an alternation of focusing and defocusing sections (as in optical lenses). In almost all synchrotrons, of either type, the ring magnet is broken into several (or many) sections separated by field-free regions that are used for injection, for rf accelerating stations, for beam observation and control mechanisms and for targeting.

Electron synchrotrons range in energy from a few tens of million electron volts up to somewhat over 1 BeV in the constant-gradient type and up to 6 BeV in the alternating-gradient variety. As in the betatron, the practical limit in energy is set by radiation losses which amount to several million electron volts per revolution in the 6-BeV machines. Since the velocity of electrons is so close to that of light, above a few million electron

volts, the accelerating frequency can be constant. To reach this energy, the smaller electron synchrotrons include some fluxbars inside the orbit to provide betatron-type acceleration and the larger ones use another accelerator as an injector such as a Van de Graaff generator or electron linac. The output from most electron synchrotrons is in the form of a continuous spectrum of x-rays, obtained when the beam strikes an internal target, or the beam can be extracted. These accelerators are usually pulsed at rates from 20 to 60 cps.

Proton synchrotrons have been built only for energies of 1 BeV and higher, since the synchrocyclotron can accelerate positive particles up to several hundred million electron volts. The constant-gradient type requires large magnetic apertures, vacuum chambers several feet wide, and massive magnets with cross sections of many square feet. It is probable that the highest energy CG proton synchrotron that will be built is the 12.5-BeV machine now operating at the Argonne National Laboratory. In the alternating-gradient synchrotrons, the stronger forces keep the protons within a cross-sectional area of a few square inches, resulting in a simple vacuum chamber and magnets about 3 feet by 3 feet, or less, in cross section. However, the stronger forces necessitate extreme precision in location and stability of the whole structure and stricter controls. The highest energy achieved to date (1964) is the 33-BeV AG proton synchrotron (half-mile circumference) at the Brookhaven National Laboratory, but a 70-BeV accelerator is under construction near Moscow, U.S.S.R. There seems to be no basic limitation to the energy achievable in AG proton synchrotrons, except cost, and design studies have been made for such machines up to 1000 BeV.

Because protons do not reach velocities close to that of light until they reach BeV energies, the accelerating systems must have a very wide frequency range that increases rapidly from the injection value to many times this value, and at the same time it must provide the correct value corresponding to the particles' energy to very high precision. In the early CG proton synchrotrons, the rf frequency is that of the frequency of revolution of the particles, but in newer accelerators, both CG and AG, a higher harmonic is used. The location and behavior of the beam is observed by placing, adjacent to the beam, "pickup electrodes" upon which charge is induced. Signals fed back from these electrodes can be used to provide corrections to the accelerating frequency program. Such control is essential in AG accelerators and is also used in some CG machines.

Because of the difficulty in providing sufficiently accurate magnetic fields at low values, other types of accelerators are used to raise the protons' energy to several MeV before injection. In the smaller CG proton synchrotrons, the injectors are usually Van de Graaff electrostatic generators of 3 to 4 MeV, but the larger synchrotrons, both CG and AG, use proton linear accelerators of 10 to 50 MeV. The time taken to complete acceleration

to the full energy is of the order of 1 second, and repetition rates vary from 10 to 20 pulses/min. Typical intensities in proton synchrotrons are 10^{11} to 10^{12} protons/pulse, and space-charge effects set an upper limit at intensities about an order of magnitude, or so, higher than this. Recently various types of instabilities have been observed at intensities below these theoretical values and the actual limits are still under investigation.

With alternating-gradient focusing, particle orbits are quite closely spaced even for large differences in momentum, and this has led to the development of Fixed-Field Alternating-Gradient (FFAG) accelerators. In these, the magnetic field can remain constant in time, but the annular magnet must have considerably greater radial width than the synchrotron's in order to contain all orbits from the injection energy to the desired top value. In the radial-sector FFAG design, the magnet is broken into wedge-shaped sectors where the magnetic field increases strongly with radius but is reversed in sign in alternate sectors. In the spiral-ridge design, the magnetic field again increases rapidly with radius and remains constant in sign, and spiraling ridges on the magnet poles give regions of stronger field. These ridges provide alternations in focusing forces as the particles cross them during their revolutions. Although these accelerators are much more costly than the pulsed synchrotrons, they can provide much higher intensities. This can be accomplished by accelerating particles to a high energy and "stacking" many groups of them at their high-energy orbit. No FFAG synchrotron has been constructed as yet for high energies although models have demonstrated their feasibility.

A variation of this principle has been used in the construction of AVF (Azimuthally Varying Field), or Sector-Focused, Cyclotrons in which the cylindrical magnets have four, or more, slightly spiraling sectors that give alternations in gap height and thus in field. The strong focusing forces and an increase in magnetic field with radius allow the particles to stay in resonance as their mass increases. Several AVF cyclotrons have been constructed for positive ions, with proton energies up to 80 MeV, and designs have been proposed up to almost 1 BeV.

As the construction of accelerators has progressed to higher and higher energies and the particles become more relativistic, one source of concern has been the limitation on the actual fraction of energy available in the center-of-mass system for the production of new particles and interesting reactions. For example, when protons with kinetic energy of 30 BeV strike a fixed target, only 5.86 BeV is available for particle production. This has led to a consideration of providing beams of equal and opposite momenta which can intersect at one or more locations and so provide their total kinetic energy in the center-of-mass system. To obtain a significant number of interactions, high intensities are required. Designs have been studied for intersecting magnetic storage rings where many pulses from existing high-energy proton synchrotrons could be collected for such

use, but none have been built as yet (1964). However, storage rings for electrons of around 500-MeV energy have been constructed at Stanford University, U.S.A., and in Europe, and investigations with these will provide information concerning the usefulness of such devices.

ACCELERATORS, VAN DE GRAAFF

The electrostatic particle accelerator originated by American physicist Robert Jemison Van de Graaff is widely used for nuclear structure research. These constant-potential accelerators make use of the electrostatic belt generator invented by Van de Graaff about 1930. They belong to the *direct* accelerator family in which the high voltage power is applied directly across the terminals of a highly evacuated multi-electrode tube. Electrified atoms or electrons from a source within the high-voltage terminal gain velocity and energy as they move along the tube axis to ground under the action of the applied electric field. As each particle emerges from the accelerator, it is moving with a kinetic energy equal to qV where q is the particle charge and V the generator voltage.

While a Rhodes Scholar at Oxford during 1927 and 1928, Van de Graaff selected the electrostatic approach to fulfill the need, much emphasized by Rutherford, for more copious sources of atomic particles comparable in energy to those spontaneously emitted from naturally radioactive materials (see ELECTROSTATICS). Subsequently, at Princeton University, Van de Graaff produced over one million volts between the spherical terminals of two small electrostatic belt generators of a new and surprisingly simple design; in 1931, he described the electrostatic belt generator principles, and their suitability for the bombardment of atomic nuclei, before the American Physical Society. The method was first applied to nuclear investigations at the Carnegie Institution of Washington in 1932. The early machines, insulated in atmospheric air, produced streams of light positive ions such as protons and deuterons homogeneous in energy and with smooth control over the voltage range of the machine. General acceptance of the Van de Graaff accelerator as the precision instrument for experimental nuclear research followed rapidly, and its further development for this purpose has been continuous since

that time. Greater compactness and higher voltage were attained by insulating the belt generator and tube with compressed gas; greater beam intensity came through improved ion source and acceleration tube technology. About 300 such accelerators were in use by 1960, producing particles and radiation with energies from 400 keV to 10 MeV. At that time, Van de Graaff accelerators for nuclear science incorporated the "tandem acceleration" principle described below. It opened the way to far higher particle energies by applying the tandem principles to multiply charged heavy atoms.

Van de Graaff accelerators can accelerate any electrified particle, including any of the 92 elements, electrons, and clumps of matter simulating micrometeorites. In addition to use in experimental nuclear physics with high-energy positive ions, Van de Graaff electron accelerators designed for voltages in the 1 to 5 MeV range are used to produce megavolt x-rays for the treatment of malignant disease and for the radiographic inspection of heavy opaque structures such as metal forgings, weldments, and rocket engines. Streams of electrons from such accelerators are also used for radiobiological and radiochemical research, and for the treatment of skin malignancies. Radiation processing studies for such

purposes as the sterilization of surgical materials, the cross-linking of polyethylene and other plastics, the deinfestation of grains, and increased shelf life of foods have often made use of Van de Graaff accelerators.

Van de Graaff Generator Operating Principles. Although a variety of electrostatic machines had been developed since the first frictionally excited generator of Otto von Guericke in the middle of the seventeenth century, all have been superseded by the Van de Graaff generator¹ because of its greater voltage capability and comparative simplicity. The essential components of the generator, outlined in Fig. 1, include a well-rounded metal terminal supported by an insulating column and an endless insulating belt system which physically conveys electric charge from ground to the high voltage terminal.

Electric charge of the desired polarity is deposited on the moving belt surface by corona from a row of metal points at a controllable voltage with respect to the lower pulley toward which they are directed. In addition to overcoming friction and windage, the motor-driven belt does work in carrying this charge from ground to the terminal potential. Transfer of the charge from belt to terminal is accomplished by again presenting a row of points toward the electrified belt. This

FIG. 1. Diagram of Van de Graaff electrostatic belt generator. Reproduced by permission of The Institute of Physics and The Physical Society from the article by R. J. Van de Graaff, J. G. Trump, and W. A. Buechner, "Reports on Progress in Physics," 11, p. 1, 1948.

time the electric field of the surface-bound charge produces the gaseous ionization needed for conduction across the point-to-belt gap. Van de Graaff pointed out that these ionized charge-transfer processes remain independent of the terminal voltage if they are located in the field-free space within the hollow terminal or below the ground plane. The current of such an electrostatic generator is limited by the maximum charge density which can be insulated in the gaseous medium surrounding the belt and the total area per second of charge-laden surface entering or leaving the terminal. To increase the current capability of the system, the return run of belt may be charged within the terminal in a similar manner but with the opposite polarity.

The potential, V , of the high voltage terminal of a Van de Graaff generator is determined by the amount and polarity of the accumulated charge on its insulated terminal. At any instant $V = Q/C$ where Q is the net positive or negative charge on the terminal and C is the capacitance of the terminal system to ground. Although the Van de Graaff generator is inherently a constant-current machine, it can be maintained steadily at the desired voltage by balancing the current arriving at the terminal against the total current delivered to the load. The load usually includes the particle current through the accelerating tube, the current through resistors which divide the terminal voltage uniformly along the supporting column, and any corona from the terminal itself arising from the high electric field at its surface. By adjusting either the belt current or the load current, the terminal voltage may be maintained at any desired value up to the maximum which can be insulated. This maximum voltage depends only on the physical size and geometry of the terminal and on the electrical strength of dielectric medium surrounding it. An isolated metallic sphere would be the ideal terminal, but modifications are necessitated by the supporting column, belt and tube.

The pair of generators built by Van de Graaff at Princeton in 1930 each had an aluminum spherical terminal 2 feet in diameter supported in air by a slender glass rod 7 feet long. A silk ribbon was employed as the insulating charge conveyor. The voltage insulated in atmospheric air between these two generators, one accumulating positive and the other negative charge, was more than twice any previously attained constant voltage.

About 5.5 million volts were insulated in air between two larger generators constructed by Van de Graaff in the early 1930's for nuclear research. This voltage required spherical terminals 15 feet in diameter supported on insulating tubular columns 25 feet high. This historic equipment, shown in an early sparking demonstration in Fig. 2, was used in a modified form for precision nuclear research at Massachusetts Institute of Technology for nearly 20 years. It is now installed at the Boston Museum of Science for demonstrations of the principles and phenomena of electrical science.

The need for still higher constant voltages for

nuclear investigations, and the desire for more compact apparatus, led to the use of high-pressure gases for the insulation of electrostatic accelerators. Today nearly all Van de Graaff accelerators operating at potentials in excess of one-half million volts are within a steel pressure tank and insulated in gases compressed to 10 to 25 atmospheres. Electronegative gases such as sulfur hexafluoride (SF_6) and "Freon" (CCl_2F_2) are now increasingly used instead of mixtures of nitrogen and CO_2 , since they insulate approximately the same voltages at one-third gas pressure.

Acceleration System. The evacuated acceleration tube, the source of positive ions or electrons, and the target to which the energized particles are directed, constitute the particle accelerating system of the Van de Graaff accelerator. The insulating length of the evacuated acceleration tube is divided into many sections by metal disk-like electrodes, each with an axial opening for the passage of the particle beam. Each disk is mounted between annular rings of glass or porcelain to form a slender vacuum-tight accelerating column. The tube electrodes take their potential from the metallic members in the generator column along which the terminal voltage is divided by resistors. The charged particles, acted upon by the electric field between these electrodes, are progressively accelerated and focused as they move through the electric fields between the electrodes. At the remote end, the beam emerges as a collimated and directed stream of energetic particles.

Tandem Acceleration and Multiply Charged Ions. Van de Graaff accelerators for nuclear science now reach higher particle energies with a given terminal voltage by switching the polarity of the accelerated particles. In the two-stage tandem diagramed in Fig. 3, negatively charged ions are produced at ground and then accelerated toward a high-voltage positive terminal. Within this terminal, the swiftly moving negative ions are stripped of electrons by passing through a thin gaseous region. The resultant positive ions continue through the tube under the second accelerating action of the positive terminal. A singly charged particle, such as a proton, thus arrives at the ground end of the system with an energy of $2qV$.

At sufficiently high energy, atoms of higher atomic number may be stripped of several or even of all their satellite electrons. An ion which lacks N electric charges during the second acceleration stage gains a total energy of $(N + 1)V$ in a two-stage tandem accelerator. Three-stage acceleration is secured by adding an additional in-line two-stage accelerator with a central negative terminal and using it to produce one stage of negative ion acceleration for injection into the second tandem. Although the light elements, hydrogen and helium, were almost exclusively used as atomic projectiles in nuclear structure physics until 1960, interest in heavier nuclei developed rapidly as higher energies became possible. It is estimated that, by applying tandem acceleration principles, a two-stage

FIG. 2. 5.5-million volt Van de Graaff generator in sparking demonstration.

FIG. 3. Diagram of two-stage tandem Van de Graaff accelerator. Reproduced from the article by R. J. Van de Graaff in "Nuclear Instruments and Methods," 8, p. 195-202, 1960, by permission of the North-Holland Publishing Co.

Van de Graaff accelerator with a 15 MeV positive terminal can produce a beam of uranium ions with energies up to 400 MeV. In large part because of the more complete electron stripping attained at higher energies, three-stage acceleration could produce uranium ions with energies over 1000 MeV.

Medical Applications of Van de Graaff Accelerators. Since x-rays are the form of electromagnetic energy, similar to light, produced by the sudden stopping of high-energy electrons, Van de Graaff accelerators are often used as x-ray sources for the treatment of malignant disease and for radiography. In this application, the high-voltage terminal is operated at negative polarity, the electrons are emitted from a tungsten source at the terminal end of the acceleration tube, and they are suddenly stopped after traversing the length of the tube by striking a water-cooled metal target, usually of tungsten or gold.

A 2 million volt x-ray generator of this type, in which a gold target is bombarded with 300 μ A of electrons, yields an x-ray intensity of 100 r/min measured 1 meter from the target in the electron direction. The quality of this radiation is closely similar in its physical properties to that of the gamma rays from radium or from the radioactive isotope cobalt 60. To equal this x-ray intensity would require over 4000 curies of cobalt 60 or 6000 grams of radium. This Van de Graaff accelerator for therapy is housed in a steel tank 3 feet in diameter and 6 feet long and is insulated by a mixture of nitrogen and CO₂ at 300 psi.

ACOUSTICS

Physical acoustics deals with the properties and behavior of longitudinal waves of "infinitesimal" amplitude in solid, liquid, or gaseous media. These waves are propagated at the velocity of

sound, or phase velocity, which is independent of frequency in a non-dissipating free medium. In such a case, the shape of a complex wave remains unchanged during its propagation, although its amplitude may change. When the velocity of sound, or phase velocity, becomes dependent on frequency, the shape of a complex wave changes during propagation and dispersion is said to occur. In such cases groups of waves comprising a limited range of frequencies travel at a velocity called the group velocity, different from the phase velocity. It is the group velocity which carries the energy of such complex waves.

Acoustic waves are dispersive (1) in a *free* medium in which viscosity, heat conduction, and molecular, thermal, or chemical relaxation cause an increase in phase velocity with frequency, (2) in a *confined* medium in a capillary tube in which viscosity causes a decrease in phase velocity with frequency, (3) in a *confined* medium in *non-dissipative* tubes of increasing cross section, where the rate of change of cross-sectional area differs from the conical (i.e., different from proportionality to the square of the distance along the tube)—examples of such tubes being the exponential and catenoidal horns, in which the phase velocity increases with decreasing frequency, (4) in non-dissipative cylindrical tubes with *flexible* walls, and (5) in waves of *finite* amplitude, where the higher-frequency components have a higher phase velocity than the lower-frequency components, a transfer of energy occurring from the lower-frequency components to the higher-frequency components.

In physical acoustics, waves are reflected, refracted, diffracted, and absorbed. They exhibit all the properties of wave motion, such as reinforcement and destructive interference. They are accompanied by pressure and particle-velocity fluctuations detectable by the ear or by instruments capable of measuring the frequency instantaneous values, and mean intensity of these fluctuations.

Geometrical acoustics is a special case of physical acoustics in which diffraction and interference are disregarded. Energies of direct and reflected waves are considered to add irrespective of relative phase, a condition applicable to incoherent (i.e., uncorrelated) waves.

Electroacoustics deals with the manner and means of energy transfer between electromechanical devices and the medium propagating sound waves. It is concerned with microphones of various types (dynamic, electrostatic, piezoelectric, magnetostrictive), loudspeakers of equivalent types (to which Maxwell's reciprocity theorem applies), and amplifiers for the faithful transfer of signals received by a microphone to those reproduced by a loudspeaker, tape recorder, or oscilloscope.

Architectural acoustics deals with the problems of distribution of beneficial sounds within buildings and with the exclusion or reduction of undesirable sounds. Here it is shown that mass and limpness of barriers such as partitions are most significant in providing high sound transmission

loss. It is also shown that sound transmission loss tests on relatively small partitions (of the order of 66×80 inches) often give significantly higher transmission loss values than the full size partitions (of the order of 100×180 inches) usually used in practice. This points up the essential need to rely on full-scale tests, rather than on smaller-scale tests, for sound insulation data. Moreover, the application of sound absorbing materials, such as acoustical tiles or fibrous sound-absorbing blankets, to walls or ceilings, have a minor effect on transmission loss through partitions, vertical or horizontal. This applies equally well to such remedial measures as blowing rock wool between studs in walls or between joists in floors or ceilings. The only significant improvement in sound transmission loss results from massive structures or from discontinuous constructions such as floating floors, heavy flexibly suspended ceilings, staggered studs or multiple leaves in walls.

In auditoriums, reflective ceilings and reflective walls, combined with convex irregularities of random design, provide for reinforcement and diffuseness of sound found so beneficial for speech and music. Reflecting surfaces, giving short time-delay reflections (about 20 msec or less), are particularly desirable in concert halls. Delays of 65 msec or more may result in echoes and speech unintelligibility.

Psychological acoustics deals with the emotional and mental reactions of persons and animals to various sounds. Here questions arise as to which sounds are acceptable to most people under various living conditions and which are not. For this purpose, various noise criteria have been developed, related to the so-called speech interference level (SIL). By definition, SIL is the average of the sound pressure levels in decibels (L_p , see below) in the three octave frequency bands 600 to 1200 cps, 1200 to 2400 cps, and 2400 to 4800-cps. The loudness level in phons (L_N , see below) of a broad-band noise (no outstanding pure tones) should be not over 22 phons (at the most, not over 30 phons) greater than the SIL, in decibels, of the background noise. Two noise control criteria, so-called NC and NCA, are designed to fulfil these conditions for various sound fields ranging from radio broadcasting studios, through bedrooms, offices, restaurants, sports arenas and factories.

Physiological acoustics deals with hearing and its impairment, the voice mechanism, and the physical effects in general of sounds on living bodies.

The frequency range of sound is divided into three somewhat overlapping regions, namely, an *audio-frequency* band ranging from approximately 20 to 20000 cps flanked by an *infrasonic* region below 30 cps and an *ultrasonic* region above 15000 cps. Human ears do not respond in general to frequencies outside the audio band, although small animals such as cats and bats do hear in the lower ultrasonic region. At one time called *supersonics*, the term *ultrasonics* is now accepted to distinguish this area of high-frequency

sound propagation from the cases of supersonic aircraft, supersonic fluid flow, and shock waves in fluids, which have to do with speeds higher than the speeds of sound.

The *strength* of a sound field is measured by its mean square pressure expressed as sound pressure level (L_p) in decibels. Decibels are logarithmic units defining the range of sound pressure levels (L_p) between the minimum audible value at 1000 cps (4db*—the threshold of hearing) for the average pair of good young (high school age) ears and the maximum audible value of L_p at which effects other than hearing (such as tickling in the ears—the threshold of *feeling*) begin to appear. This upper limit shows up at about 120 db at 1000 cps.

Higher values of L_p (e.g., 130 db) begin to cause pain in the average ear, and values of 160 db may well cause instantaneous physical damage (perforation) to the tympanic membrane. The minimum audible sound pressure, p_0 , at 1000 cps is internationally accepted as 0.0002 microbars rms (i.e., 0.0002 dynes/cm², rms), and the sound pressure level at any other rms value of sound pressure, p , irrespective of frequency, is given by $L_p = 20 \log_{10} (p/p_0)$ db. The bel (seldom used) is simply equal to 10 decibels. The bel appears first used in connection with power loss in telephone lines and is named in honor of Alexander Graham Bell.

Other reference pressures, p_0 , may be used in special applications, instead of 0.0002 microbar, so it is essential to specify the reference pressure when quoting values of L_p .

The *loudness* of a sound field is judged by the ear in the audio frequency range. Loudness judgments by groups of observers have established a *loudness level* scale. The loudness level (L_N) in phons is arbitrarily taken equal to the sound pressure level L_p in db at the reference frequency of 1000 cps over the range from the threshold of hearing to the threshold of feeling. Jury judgment of equality in loudness between test tones at different frequencies (f) and 1000-cps reference tones of known sound pressure level (L_p) have established *equal loudness* contours (contours of constant L_N) in the L_p - f plane.

These contours show in general a marked decrease in ear sensitivity to sounds at frequencies below about 200 cps, and this decrease is much more pronounced in the lower loudness levels. For example, at 50 cps the 4-phon contour has an L_p of about 43 db, the 80-phon contour about 93 db. At higher frequencies, the ear shows some 8-db increase in sensitivity in the region around 3500 cps, then a loss in sensitivity beyond about 6000 cps. These characteristics of hearing are significant in the design of lecture and music halls, noise-control devices, and high-fidelity audio equipment.

Also based on jury judgments, a scale of *loudness*, N , (in sones) has been established for sounds (for pure tones and for broad band noise). On

* 0 db at 1000 cps is defined in older work as the threshold of hearing.

this scale, a given percentage change in some value denotes an equal percentage change in the subjective loudness of the sound. The scale provides single numbers for judging the relative loudnesses of different acoustical environments, for evaluating the percentage reduction in noise due to various noise control measures, and for setting limits on permissible noise in factories, from motor vehicles, etc.

Loudness N is related to loudness level L_N in the range 40 to 100 phons by the equation $\log_{10} N = 0.03 L_N - 1.2$. A loudness of 1 sone corresponds to a loudness level of 40 phons and is typical of the low-level background noise in a quiet home.

Various methods are available for estimating loudness of complex sounds from their sound pressure levels in octave, half-octave, or third-octave bands. For traffic noises, readings on a standard sound level meter using the A-scale (which incorporates a frequency-weighting network approximating the variation of ear sensitivity with frequency to tones of 40-db sound pressure level) appear to correlate reasonably well with jury judgments of vehicle loudness.

The *noisiness* of a broad-band noise is more related to the annoyance it causes than to its loudness. Thus, corresponding to the scale of sones created to measure loudness, a scale of *noys* has been developed as a measure of the noisiness of jet aircraft noise in particular. Noys give more importance to the high-frequency bands of noise and less importance to the low-frequency bands than do sones. Also, corresponding to the scale of loudness levels in phons, there has been established a scale of *perceived noise levels* in PN db. Rules have been established for converting sound pressure level measured in octave bands, half-octave bands and third-octave bands into noys and then into PN db. Although originally developed as a means for the assessment of the "noisiness" of jet aircraft flying over inhabited communities, the concept of noisiness is being applied to traffic and other broad band noises.

ADSORPTION AND ABSORPTION

When a porous solid such as charcoal is exposed, in a closed space, to a gas such as ammonia, the pressure of the gas diminishes and the weight of the solid increases; this is an example of the adsorption of a gas by a solid. It is termed physical adsorption because the forces bringing it about are the "van der Waals" forces of attraction which act between the molecules of the gas and the atoms or ions comprising the solid. It is now known that all solids, whether porous or nonporous, will adsorb all gases physically, whereas the phenomenon of *chemisorption* is specific in nature. Thus hydrogen is chemisorbed by transition metals such as nickel or iron but not by oxides such as alumina.

In physical adsorption the amount, say w grams, of gas or vapor taken up per gram of solid depends greatly on the nature of the gas and of the solid, as well as on the pressure p and the temperature T . In mathematical form, $w = f(p, T, \text{gas}, \text{solid})$. For a given gas and solid at a fixed temperature, w depends only on pressure, and the relationship between w and p (i.e., $w = f(p)_{T, \text{gas}, \text{solid}}$) is called the *adsorption isotherm*. Data of adsorption are usually quoted in the form of the adsorption isotherm of the gas or vapor under consideration (the "adsorbate") on the given solid (the "adsorbent"). For vapors it is more appropriate to express the isotherm in terms of relative pressure so that $w = f_0(p/p_0)_{T, \text{vapor}, \text{solid}}$, where p_0 is the saturated vapor pressure of the adsorbate at the temperature of the experiment.

With the great majority of solids, the isotherm at the low-pressure end is concave towards the pressure axis. Its further course depends on the nature of the solid: if the solid is nonporous (e.g., a powder) the isotherm reaches a point of inflection at a relative pressure in the region 0.1 to 0.3 and thereafter turns upwards (Type II isotherm); if it is porous, with pores having radii between tens and hundreds of angstroms in diameter, the form of the isotherm is similar, except that at pressures near saturation it bends over and becomes almost horizontal; it also shows a *hysteresis loop* in the middle range of pressures, the desorption branch lying above the adsorption branch (Type IV isotherm). If the solid contains an extensive series of pores of molecular width ($\sim 10\text{\AA}$), the isotherm shows no point of inflection

but continuously diminishes in slope and finally becomes nearly horizontal (Type I isotherm).

Measurements on solids having a known surface area have shown that at low pressures the adsorbed layer is only one molecule thick and as pressure increases the molecules in this "monolayer" become more and more crowded, till at or near the point of inflection in the isotherm the monolayer is completely full up. Further increase in pressure then leads to the formation of a multimolecular layer—a "multilayer"—of gradually increasing thickness.

Adsorption is an exothermic process so that by elementary thermodynamic principles the amount adsorbed by a given solid at a given pressure must diminish as temperature increases. The differential heat of adsorption \bar{q} [i.e., the limit of the ratio $\delta q/(\delta w/M)$ where δq is the heat evolved when the adsorption increases by $\delta w/M$, M being the molecular weight of adsorbate] is rather larger than the latent heat of condensation L of the adsorbate. The value of \bar{q} depends somewhat on the amount adsorbed; it is relatively high for small adsorptions—perhaps about $2L$ —then diminishes as w increases, till in the multilayer region it scarcely exceeds the latent heat. There is usually a low maximum ($\sim 1.3L$ or so) in the region where the monolayer is just complete. The values quoted are only by way of example, and minor, generally unpredictable, differences are found between one system and another. The falling branch of the \bar{q} vs w curve is usually ascribed to heterogeneity of the surface (adsorption occurring first on the more "active" parts of the surface), and the branch rising to the maximum is probably produced by mutual attraction of the molecules within the adsorbed film.

Since physical adsorption results from van der Waals forces, the greater the condensability of the gas or vapor as measured by its boiling point or its critical temperature, the greater is the amount of gas or vapor adsorbed at a given pressure. Thus at room temperature and atmospheric pressure, the "permanent gases" such as hydrogen or nitrogen are only slightly adsorbed even on a good adsorbent such as charcoal, while carbon dioxide is more adsorbed, and benzene and carbon tetrachloride are strongly adsorbed. At very low temperatures the adsorption is correspondingly greater, so that nitrogen at its boiling point of -195°C has an adsorption, on a given solid, comparable with that of benzene at 25°C . For the adsorption to be readily measurable, however, the solid needs to have a relatively large area—a completed monolayer of nitrogen, 1 square meter in extent, weighs only 0.3 mg, for example—so that adsorption phenomena may escape notice unless the solid is "highly disperse," i.e., has an area exceeding several square meters per gram.

Numerous attempts have been made to interpret the detailed course of the different types of isotherm theoretically; but only limited success has been achieved because the models used are necessarily oversimplified and can rarely correspond in detail to the complex systems encoun-

tered in practice. However, it is generally agreed that at or near the point of inflection, the monolayer is complete; thus by assuming a value for the cross-sectional area of an adsorbed molecule, it is possible to estimate from a Type II or a Type IV isotherm the surface area of the solid (the "Brunauer-Emmett-Teller" method). Further, from the course of the desorption loop of a Type IV isotherm, by assuming the adsorbate to be condensed as a liquid in pores which are regarded as cylinders, and by applying the Kelvin equation, one can calculate the pore size distribution of the solid; because of the assumptions made, the accuracy of the method is severely limited, but it is useful for comparative purposes and is virtually the only method applicable in the pore size range of tens to hundreds of angstroms.

Chemisorption results from valency forces—from the sharing of electrons between the adsorbate molecule and the adsorbent—so that, in effect, a surface chemical compound is formed. Chemisorption is characterized by a high heat of adsorption (of the order of tens of kilocalories per mole, in contrast to the few kilocalories of physical adsorption) and by difficulty of reversal: to desorb a chemisorbed gas in a reasonable time requires a temperature much higher than that at which the chemisorption occurred. Even so the adsorbate may be released in a chemically changed form; thus carbon monoxide chemisorbed on zinc oxide at room temperature is desorbed as carbon dioxide at 300°C .

Chemisorption is an essential primary step in heterogeneous catalysis. At least one of the reactants must be chemisorbed on the surface of the catalyst, and each of its molecules then forms, on the surface, a "transition complex" with a chemisorbed molecule of the second reactant B, or with a molecule of B which hits it directly from the gas phase.

Physical adsorption is an extremely widespread phenomenon, frequently unwanted. The adsorption of water vapor by chemicals, by textiles, by building materials and by glass is frequently troublesome and can only be avoided by taking extreme precautions; sometimes, however, the adsorption of water may be beneficial, and it plays an important role, for instance, in the hygiene of clothing.

Adsorption, whether physical or chemical, also reduces the adhesion, and therefore the friction, between solids; gases can accordingly act as lubricants. In addition, adsorption diminishes the tensile strength of brittle solids; the breaking stress of glass when exposed to nearly saturated water vapor is four times less than when exposed to a vacuum. This is because of the part played by the adsorbed film at the tip of fine cracks in the brittle solid; the film reduces the free surface energy (in the thermodynamic sense) of the solid. Adsorption also causes a small (a fraction of 1 per cent) expansion of the solid, but the swelling pressure set up—i.e., the pressure which would have to be exerted on the solid to prevent expansion—is very high and may reach many atmospheres. Stresses set up in structures made up of

porous solids, such as cement and mortar, when they take up or lose vapors, particularly water, may be so great as to cause cracking.

Absorption is said to occur when the molecules of the gas or vapor actually penetrate into the solid phase itself, so that a solid solution is formed; hydrogen is absorbed by iron at elevated temperature in this way, and many synthetic polymers absorb water vapor; benzene vapor is extensively taken up by rubber and water vapor by gelatin. Extensive swelling occurs and if the solid is mechanically weak, the absorption may continue until the system becomes a liquid. An absorption isotherm (analogous to the *adsorption* isotherm discussed earlier) can be determined, but is generally complicated and is best handled theoretically as a branch of solution thermodynamics.

In *adsorption from solution*, when a solid having appreciable surface area (say ~ 1 square meter per gram) is shaken up with a solution of substance A in solvent B, both A and B are adsorbed, but to different relative extents. This manifests itself in a change in the composition, e.g., a change Δx_1 in the mole fraction of A in the solution. The problem is thus more complicated than in the adsorption of gases, and the measured isotherm—the curve of Δx_1 against x_1 —is not susceptible to any simple theoretical treatment. In a *dilute* solution of A, however, A is always relatively more adsorbed than the solvent B; and if A is colored, the resulting diminution in the concentration of A in the solution will be readily detected by eye or colorimetrically.

AERODYNAMICS

Aerodynamics is the science of the flow of air and/or of the motion of bodies through air. It is usually directed at achieving flow or flight with the maximum efficiency. Aerodynamics is a branch of Aeromechanics; the other main branch is *Aerostatics* (lift of balloons, etc.). In popular usage *Aerodynamics* differs from *Gasdynamics* in that the latter considers other gases and products of combustion (and combustion); from *Aerophysics* which implies a substantial meteorological contribution; and from *Hydrodynamics* which implies employing a medium of density approximating that of useful bodies in it, and not infrequently a sharp limit to its extent (i.e., a water surface).

Aerodynamics is conveniently divided into low and high speed regimes. (The latter in the

articles on COMPRESSIBILITY, FLUID DYNAMICS and SHOCK WAVES; here low speed aerodynamics is discussed.)

The many facets of aerodynamics include: (1) aerodynamic performance, (2) aerodynamic design, (3) aerodynamic loads, (4) aerodynamic structures, (5) aero-elasticity, (6) aerodynamic heating, (7) aerodynamic compressibility, and (8) aerodynamic research for all of the above.

The computation of aerodynamic effects are based on four laws (given as adapted for fluids):

(1) *Newton's Second Law*: "A force applied to a fluid results in an equal but opposite reaction which in turn causes a rate of change of momentum in the fluid."

(2) *The Equation of State*: (also called the Gas Law): "The product of pressure and volume of a gas, divided by its absolute temperature, is a constant."

(3) *The Continuity Equation*: "The mass that passes a station in a duct, or in a natural tube bounded by streamlines in a given time, must equal that passing a second station in the same time."

(4) *The Energy Equation*: "The total energy in a mass of air remains constant unless heat or work is added or subtracted."

The above relations, written algebraically and limited or combined, yield a vast array of equations used to calculate the practical problems of aerodynamic. One of the *equations* thus derived is due to Bernoulli and is widely used in low speed aerodynamics. It states that in free flow the sum of the static and dynamic pressures is a constant. Static pressure is that pressure which is equal in all directions; dynamic pressure is the pressure rise realized by bringing the fluid to rest. Bernoulli's equation states that as air speeds up, its pressure falls, thus explaining the "lifting suction" as the airstream traverses the curved upper surface of a wing.

The overwhelmingly important *law* of low speed aerodynamics is that due to Newton (1, above). Thus a helicopter gets a lifting force by giving air a downward momentum. The wing of a flying airplane is always at an angle such that it deflects air downward. Birds fly by pushing air downward. Propellers and jet engines make a forward force ("thrust") by giving air a rearward momentum. In the above statements, it is much more accurate to use the expression "downward (or rearward) momentum," rather than "downward (or rearward) velocity," as less dense air at high altitudes produces smaller forces for comparable velocity changes. Forcing the air downward does not occur instantaneously; it takes place over the lifting surface. Indeed, the motion reaches ahead of the airplane so that some downward velocity occurs before the airplane arrives. Thus, airplanes (helicopters, birds, etc.) are always "flying uphill" which is another way of saying it takes a force to fly even when the air is considered frictionless. This force is used to push air *forward*, and is called "drag due to lift." It *increases* as an airplane *slows down* or *flies higher*, and it may be reduced (for low speed aircraft) by *increasing* the

wing span. Supersonic aircraft, operating under the same laws, but in a different manner, still have a drag due to lift which increases as above, but is reduced designwise by *reducing* the span. Hence the new airplanes whose wings crank back for high speed flight. (The "uphill" concept has an analogy in the rolling resistance of a wheel. The weight a wheel carries deflects the surface on which it rests so that it sits in a "gully." Either way it rolls, the path is uphill).

A second important phenomena (but not a "law" in the sense that it cannot be circumvented) is the manner in which air flows over say, an airplane surface. Away from the surface some freestream velocity exists. As the surface is approached the local velocity becomes less than freestream and finally becomes zero at the surface. The zone in which the air is appreciably slower is called the *boundary layer*. Slowing the air reduces its momentum, and by Newton's law (above), a force is produced which acts in a direction to slow the airplane. Like forward force needed to produce lift, this *frictional drag* force must have a forward force supplied from somewhere to balance it. For high speed aircraft a heating occurs in the boundary layer which requires additional force. Skin friction drag is *decreased* by reducing the amount of surface the air scrapes against (i.e., making the aircraft smaller) and by *flying slower or higher*—essentially the opposite of the actions which reduce the drag due to lift. Thus the science of aerodynamics seeks the most efficacious melding of the two types of losses. Factors which must be added include providing space for fuel and people, and enough wing to yield a reasonable landing speed. The drag due to lift and the drag due to friction are balanced by the forward thrust provided by the propeller or jet engine (which also operates by Newton's law). However, this is not enough. The distribution of lift on wing and tail must be so located that the aircraft is aerodynamically balanced. Like a child's swing, upon being disturbed it should tend to return to its original ("trimmed") condition.

In the above paragraphs the concern has been for aerodynamic efficiency through optimum design for optimum performance. After these have been achieved (by studies of previous designs and tests in *wind tunnels*) the aerodynamicist provides aerodynamic loads to which an aero-structural engineer must design. Aero-structural design is one of the most challenging of all design problems as the loads must be carried by minimum weight. Aeroplanes carry no "factor of safety" (sometimes called "factor of ignorance"). The aerodynamic-loads engineer furnishes the maximum air loads the aircraft is ever expected to see; the structure is designed to withstand these loads without being permanently bent. If it ever sees a greater load it will be bent or destroyed; there is about a 50 per cent difference between maximum no-permanent set load and catastrophic destruction, depending on the material of which the aircraft is constructed.

In an effort to keep aerodynamic structures light, they often become flexible, and, in turn,

become susceptible to flutter, a motion similar to that of a flag in a wind. The motion gets worse with speed. It is the job of the aero-elasticity engineer to assure that flutter will not occur, usually through a redistribution of internal weights (fuel, etc.) and, rarely, through strengthening the structure.

At the higher speeds, the performance, loads, structures and elasticity problems are greatly worsened by the aerodynamic heating which occurs. This is discussed in the article on COMPRESSIBILITY.

Aerodynamics is not only concerned with aircraft. The wind loads on signs, buildings, trees; the aerodynamics drag of autos, boats, trains; the air pollution from smoke stacks of factories and ships; the evaporation of open water; the blowing of sand and snow; and the internal losses of air-conditioning ducts—all deserve and are getting scrutiny by aerodynamicists. The forces on all are proportional to the rate of change of momentum they give, or are given by the air, and all have friction drag in their boundary layers. Aerodynamic research scientists seek to further understand and improve the air flow involved in each.

Aerostatics. Aerostatics is the science of making things (balloons, zeppelins, etc.) statically buoyant in the air. It is a branch of *Aeromechanics*; the other branch is *Aerodynamics*.

The basic principle of aerostatics is due to Archimedes "A body immersed in a fluid (or gas) is buoyed up by a force equal to the weight of the fluid (or gas) displaced." Thus for buoyancy the weight of structure plus the weight of the contained gas must equal the weight of the air displaced.

Wind Tunnels. Wind tunnels are devices which provide an airstream of known and steady conditions in which models requiring aerodynamic study are tested. The essential elements of a tunnel are

- (1) A drive system consisting of either a compressor for continuous operation or a tank of compressed air for intermittent operation;
- (2) A test section in which models are held and their orientation is changed;
- (3) Instrumentation capable of reading force, pressure, and optical effects produced by the model;
- (4) An air efflux system consisting of free exit to the atmosphere or to a vacuum tank, or a tunnel returning the air to the compressor.

There are approximately 500 wind tunnels in the country, ranging in test section size from 1 inch \times 1 inch to 30 feet \times 60 feet, with speeds from 50 to 7000 mph.

ALTERNATING CURRENTS

Definition of Alternating Current. An alternating current is a periodic function of the time, the function being such that the average value is zero. A special case of an alternating current is shown in Fig. 1. The square wave is clearly periodic, and in any one cycle, the area under the curve above the horizontal axis is equal to the area below the horizontal axis. If the two areas are not equal, the current may be described as an alternating current superposed on a direct current, provided the resultant current varies in a cyclic manner.

FIG. 1. A square wave alternating current.

In general, any alternating current may be considered to be the sum of a Fourier series of sinusoidal waves. For example, the square wave shown in Fig. 1 may be written as

$$\frac{4A}{\pi} (\sin 2\pi ft + \frac{1}{3} \sin 6\pi ft + \frac{1}{5} \sin 10\pi ft + \dots)$$

where A is the amplitude of the square wave, f is the frequency in cycles per second, and t is the time in seconds. Since any alternating current may be expressed as the sum of a series of sinusoidal terms, the remainder of this article will be devoted to a discussion of sinusoidal voltages and currents.

Root-mean-square Value. The equation for an alternating current i may be written as

$$i = I_m \sin(\omega t - \delta) \quad (1)$$

where I_m is the maximum or peak value of the current, ω is 2π times the frequency f in cycles per second, and δ is a phase angle. A graph of the current i is shown in Fig. 2. Since the positive and negative loops are mirror images, the average value of the current over a complete cycle is zero. The latter statement is valid for all alternating currents and, hence, gives no information about a particular alternating current.

FIG. 2. A sinusoidal alternating current.

A useful way of stating the magnitude of an alternating current is to give its effective or root-mean-square value. The term root-mean-square is derived from the idea of taking the square root of an average square of the current. Thus, by definition, the effective value I_e of the current i given by Eq. (1) is

$$I_e = \sqrt{\frac{\omega}{2\pi} \int_0^{2\pi/\omega} I_m^2 \sin^2(\omega t - \delta) dt} \quad (2)$$

where $2\pi/\omega$ is the time for one cycle. In effect, the quantity under the square root sign is the sum of the squares of the currents during one cycle divided by the time for one cycle. The value of I_e may be found by performing the integration. The result is

$$I_e = \frac{I_m}{\sqrt{2}} = 0.707 I_m \quad (3)$$

Clearly, the effective value of a sinusoidal alternating current is 70.7 per cent of the maximum or peak value. Similarly the effective value of a sinusoidal voltage is 70.7 per cent of the maximum or peak value.

Alternating-current Series Circuit. A simple alternating-current series circuit is shown in Fig. 3. At the instant considered in the diagram, the current is in the direction shown. The circuit consists of a generator connected in series to a pure resistance R , a pure inductance L , and a capacitance C . It is important to understand the relationship of the current to the potential difference across each element. In each case, the best starting point is a basic definition. According to Ohm's law for a pure resistance,

$$R = \frac{V_R}{i} \quad (4)$$

FIG. 3. An ac series circuit.

where V_R is the voltage drop across the resistance. The inductance L of a coil is given by

$$L = \frac{N\phi}{i} \quad (5)$$

where N is the number of turns and ϕ is the magnetic flux passing through one of the turns of the coil as a result of the current i . Writing Eq. (5) as

$$Li = N\phi$$

and then differentiating both sides, we obtain

$$L \frac{di}{dt} = N \frac{d\phi}{dt} \quad (6)$$

According to Faraday's law, the right-hand side of Eq. (6) is the magnitude of the induced emf. The left-hand side, $L di/dt$, therefore, is the voltage drop V_L across the inductance L . Finally, the capacitance C is by definition

$$C = \frac{q}{V_C} \quad (7)$$

where q is the instantaneous charge on the positive plate and V_C is the drop in potential in going from the positive plate to the negative plate.

The relation between the impressed voltage $V_m \sin \omega t$ and the instantaneous current i follows from Kirchhoff's law that the sum of the differences in potential in going around a complete circuit must be zero. At the instant shown in Fig. 3, there is a potential rise $V_m \sin \omega t$ in going from A to B and there are potential drops, V_R , V_L , and V_C in traversing the rest of the circuit. According to Kirchhoff's law

$$V_m \sin \omega t - V_R - V_L - V_C = 0$$

$$V_m \sin \omega t - Ri - L \frac{di}{dt} - \frac{q}{C} = 0$$

Since the current is the rate of flow of charge

$$i = \frac{dq}{dt} \quad (8)$$

It is now possible to express the current i as a function of t . The result neglecting initial transient effects is

$$i = \frac{V_m \sin(\omega t - \delta)}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \quad (9)$$

where $\tan \delta = (\omega L - 1/\omega C)/R$. The phase angle δ is the angle by which the current i lags behind the impressed voltage.

The maximum or peak value of i is

$$I_m = \frac{V_m}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}}$$

If both sides of this equation are divided by $\sqrt{2}$, we obtain

$$\begin{aligned} \frac{I_m}{\sqrt{2}} &= \frac{V_m/\sqrt{2}}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \\ I_e &= \frac{V_e}{\sqrt{R^2 + (\omega L - 1/\omega C)^2}} \end{aligned} \quad (10)$$

Equation (10) states the relation between the effective value or the current and the effective value of the impressed voltage.

Impedance and Reactance. The denominator of Eq. (10) may be defined as the impedance Z of the circuit. We may therefore write

$$I_e = \frac{V_e}{Z} \quad (11)$$

Equation (11) is similar in form to Ohm's law, Eq. (4). The impedance Z is the square root of the sum of the squares of two terms. The first is the resistance R , and the second is $\omega L - 1/\omega C$. The latter is called the reactance. The quantity ωL is the inductive reactance whereas $1/\omega C$ is the capacitive reactance. If the inductive reactance is greater than the capacitive reactance, the phase angle δ is positive and the current lags behind the voltage. If the inductive reactance is less than the capacitive reactance, the current leads the voltage.

Vector Diagram. The current and the various voltages may be related in a meaningful way by means of a vector diagram. Equation (10) may be rewritten as follows:

$$V_e = \sqrt{R^2 I_e^2 + (\omega L I_e - I_e/\omega C)^2} \quad (12)$$

Equation (12) implies that V_e is the resultant of a vector RI_e at right angles to a vector $\omega L I_e - I_e/\omega C$. This is shown in Fig. 4. The current I_e is drawn along the horizontal axis, and the effective voltage drop across the resistance, RI_e , is also drawn along this axis. The effective voltage drop across the coil is $\omega L I_e$, and this potential difference is drawn along the positive vertical

axis. Finally, the effective potential drop across the capacitor is $I_e/\omega C$, and this vector is drawn along the negative vertical axis. The resultant of the three vectors is V_e , in agreement with Eq. (12).

FIG. 4. A vector diagram for an ac series circuit

Resonance. If the capacitance C can be varied, the current I_e will be a function of C in accordance with Eq. (10). When

$$\omega L = \frac{1}{\omega C} \quad (13)$$

the effective current will be a maximum. The circuit is then said to be in resonance. Actually, the inductance L or the angular frequency ω may be varied instead of the capacitance C . The circuit will be in resonance whenever Eq. (13) holds. At resonance, the impedance Z is equal to R , and the circuit, under such circumstances, acts as though it contains resistance only. The process of obtaining resonance is called tuning the circuit.

Average Power. The potential difference V across an ac generator at any instant is the work required to transfer a unit charge from the negative to the positive terminal. The work done in transferring a charge dq is consequently $V dq$, and the work done per unit time is

$$P = \frac{V dq}{dt} \quad (14)$$

where P is, by definition, the instantaneous power and dt is the time interval to transfer the charge dq . Since

$$i = \frac{dq}{dt}$$

Eq. (14) may be written

$$P = Vi$$

The instantaneous power is the product of the instantaneous voltage and current.

When alternating current circuits are con-

sidered, the average power \bar{P} rather than the instantaneous power is of interest. By definition

$$\bar{P} = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} Vi dt \quad (15)$$

where, as before, $2\pi/\omega$ is the time for a complete cycle. The average power may be evaluated by making the following substitutions in Eq. (15):

$$V = V_m \sin \omega t$$

$$i = I_m \sin (\omega t - \delta)$$

The result is

$$\bar{P} = \frac{1}{2} V_m I_m \cos \delta \quad (16)$$

Equation (16) may be rewritten

$$\begin{aligned} \bar{P} &= \frac{V_m}{\sqrt{2}} \frac{I}{\sqrt{2}} \cos \delta \\ \bar{P} &= V_e I_e \cos \delta \end{aligned} \quad (17)$$

Evidently, the average power is the effective voltage times the effective current multiplied by the cosine of the phase angle. In this connection, $\cos \delta$ is called the power factor. Equation (17) may be interpreted to mean that only the component of V_e in phase with I_e contributes to the average power. The other component may be said to be wattless. Since

$$V_e = I_e Z$$

and

$$\cos \delta = \frac{R}{Z}$$

Eq. (17) may be written as follows:

$$\bar{P} = I_e^2 R \quad (18)$$

From the latter form, it may be concluded that the average power is the average rate at which heat is developed in the circuit. Equation (18) also shows that a direct current having a value I_e would produce the same heating effect as an alternating current having an effective value I_e .

The Complex-number Method. In the foregoing, an alternating-current series circuit was discussed by representing voltages as vectors in the real plane. For more complicated circuits, this method is too clumsy. It is much more convenient to deal with vectors analytically by utilizing the i -operator. By definition,

$$j = \sqrt{-1}$$

When a real number is multiplied by j , it becomes an imaginary number. In other words, a point on the real axis is rotated through 90 degrees so that it becomes a point on the imaginary axis. The "complex" impedance of a series circuit may thus be written

$$Z = R + j\left(\omega L - \frac{1}{\omega C}\right) \quad (19)$$

since the reactance may be considered to be at right angles to the resistance. When several impedances are connected in series, the total complex impedance is

$$Z = Z_1 + Z_2 + Z_3 + \cdots \quad (20)$$

and, when several impedances are connected in parallel, the total impedance is given by

$$\frac{1}{Z} = \frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} + \cdots \quad (21)$$

The effective voltage V across the generator may be considered to be a vector along the real axis. The effective current I furnished by the generator is therefore

$$I = \frac{V}{Z} \quad (22)$$

By solving Eq. (22), the magnitude of I and the phase relation between I and V may be found. Although new mathematical techniques are needed, the saving of time usually justifies the use of the complex number method of handling complicated ac circuits.

ANTENNAS

Communication systems, characteristically, consist of cascaded networks, each network designed to carry out some operation on the energy conveying the information. In radio communication systems, antennas are the networks serving to transfer the signal energy from circuits to space and, conversely, from space to circuits. In circuits, the flow of energy is restricted to one or the other of two directions. The effectiveness of transfer of energy between the antenna

and the adjacent circuit element is, therefore, determined solely by the terminal impedance of the antenna and that of the adjacent circuit. The knowledge of the antenna terminal impedance over the desired frequency range, therefore, fully describes the joint performance of the antenna and the circuit element.

The relationship between the antenna and space, however, is much more complex. The distribution of the radiated energy varies with the direction in space and with the distance from the antenna. This gives rise to the directive properties of the antenna. Further, the energy is radiated in the form of an electric and a magnetic field. These are vector quantities which, at a distance from the source, are at right angles to each other and to the direction of propagation. The planes in which these vectors are located, and whether they are stationary or rotate with time, determine the polarization of the radiated field. The performance of an antenna can, therefore, be fully described only by specifying several parameters, such as radiation pattern, gain, and polarization. It is convenient, in discussing antenna properties, to consider the antenna as a radiating rather than a receiving network. The antennas are, however, linear networks and are subject to the law of reciprocity.¹ The performance of an antenna, therefore, in terms of radiation pattern, gain, or polarization is the same, irrespective of whether the antenna radiates or absorbs radiation.

Except for the immediate neighborhood of the antenna, referred to as the "near-field region" of the antenna, radiated energy propagates radially from the antenna, and the radiation intensity* varies inversely as the square of the distance from the antenna. This is a propagation effect. In discussing the antenna performance, it is customary to disregard this and to represent the distribution of the radiated power as a function of the two direction angles only. Such a distribution is commonly represented graphically and is then known as the radiation pattern of the antenna. The radiation patterns can take a variety of forms. Sometimes they are in the form of a polar diagram, with the radial distance proportional to either field strength* or intensity. The intensity may be represented linearly, as power, or logarithmically, in decibels.² For representing the directive properties of an antenna in all directions, contours of equal radiation intensity may be plotted, with the two direction angles as abscissas and ordinates, respectively.

The directive properties of an antenna also lead to the concept of antenna "gain." The directive gain of an antenna in a specified direction is the radiation intensity in that direction compared to what it would be if the total radiated power were distributed equally in all directions. For some applications, such as point-to-point communication, high values of antenna gain are

* In this discussion, radiation intensity has the dimensions of power flow per unit area, normally, watts per square meter. Electric field strength, on the other hand, is in volts per meter.

desired because such antennas concentrate the available power, thus effectively increasing it. Conversely, in receiving applications, such antennas are more responsive to radiation arriving from one direction. For other applications such as broadcasting, antennas with low directivity may be desired.

The gain of an antenna is dependent principally upon the size of the antenna, expressed in wavelengths. The larger the antenna, the greater is likely to be its gain. The values of gain for different antennas range from 1.5 for an electrically small dipole to hundreds and even thousands times that. In practice, antenna gains are usually expressed logarithmically, in decibels. For the low-frequency end of the radio spectrum (15 kc/sec to 3 Mc/sec), antennas, although large physically, are relatively small in terms of wavelengths. Therefore, the directive gains of these antennas seldom exceed 3 (4.8 db). In the high-frequency band (3 to 30 Mc/sec), which is used principally for long-distance communication, antenna gains of 10 to 100 (10 to 20 db) are frequently encountered. At microwave frequencies, where the wavelengths are a fraction of a meter, gains of several hundred, and even thousand times (20 to over 30 db), are common.

When an antenna has one or more of its dimensions significantly larger than a wavelength, its radiation pattern is likely to have more than one maximum. The radiation pattern, in such cases, is said to have a lobe structure. That part of the radiation pattern which encompasses the direction of the largest maximum and the radiation immediately to each side of it, is referred to the main lobe. The radiation about the minor maxima is referred to as the secondary or side lobes. One of the frequent goals in antenna design is the reduction in the levels of secondary lobes. These may, at times, be a source of interference to other transmissions.

In common with light, radio waves consist of electric and magnetic fields at right angles to each other and to the direction of propagation. The orientation of these fields relative to the observer determines the polarization of the wave. In radio terminology, the orientation of the electric vector of a radio wave is taken as the direction of polarization. Thus, if the electric field vector is parallel to the ground, the radio wave is termed "horizontally polarized." Although the polarization of the energy radiated by an antenna, in general, varies with the direction, an antenna is usually designated as being horizontally (or vertically, or circularly, etc.) polarized, depending on the polarization of its radiation in the direction of the main lobe maximum.

The importance of polarization in radio engineering lies principally in the different reflective properties of the ground for waves with electric field parallel to the ground and those normal to the ground. Different radio services are served best by different polarizations. Antennas for use in the low-frequency end of the radio spectrum, 15 kc/sec through about 3 Mc/sec, are almost invariably vertically polarized. This includes the

AM broadcast band. In the high-frequency band, 3 to 30 Mc/sec, both horizontal and vertical polarizations are used. For FM and television broadcast service in the United States and many other countries (but not in the United Kingdom), horizontal polarization is employed.

The types and variations of antennas encountered in practice are extremely numerous. Each type has some advantage over the others for some specific requirement. Among some of the more important and frequently encountered requirements are those for operating bandwidth, high radiation efficiency, specified degree of directivity, whether high or low, and polarization. A few of the representative types of antennas frequently encountered in practice are illustrated in Fig. 1, 2, and 3. Figure 1 shows two of the

Fig. 1. Two types of elementary radiators: (a) Monopole over ground. (b) A dipole.

elementary types of radiators, a monopole and a dipole. A monopole, shown in Fig. 1(a), in one form or another, is employed almost exclusively throughout the low-frequency end of the radio spectrum. The dipole, shown in Fig. 1(b), is somewhat more versatile, as it can be oriented to give either horizontal or vertical polarization. It is frequently used as an elementary radiator in large array-type antennas.

Figure 2 presents two, highly directive, but otherwise radically different, types of antenna. The rhombic antenna shown in (a) has broadband properties and is used widely in point-to-point communication service. The Yagi antenna displayed in (b) illustrates a relatively compact antenna with high gain for its size. Its operating frequency band is quite narrow.

The last figure, Fig. 3, shows two antenna types frequently used at microwave frequencies. The horn antenna is used generally where moderate directivity suffices. The parabolic antenna, on

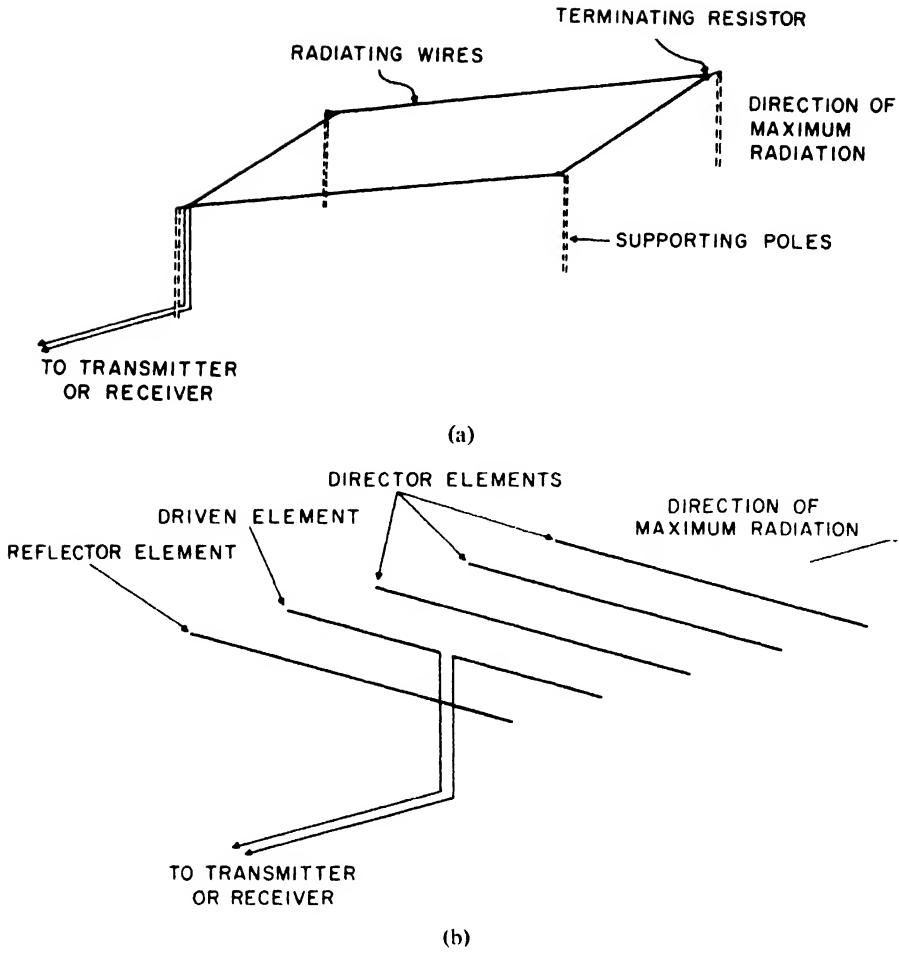

FIG. 2. Examples of directive antennas: (a) Rhombic antenna. (b) Yagi antenna.

FIG. 3. Microwave-type antennas: (a) Horn antenna. (b) Parabolic-reflector antenna.

the other hand, is used for high-gain applications and is a quasi-optical device.

For a more complete listing of antenna types and their discussion, the reader is referred to texts on antennas such as the "Antenna Engineering Handbook."³ For additional discussion of the principles underlying antennas, texts by Kraus⁴ and Schelkunoff and Friis⁵ are suggested.

ANTIFERROMAGNETISM

Antiferromagnetism is the most common form of magnetic order. It is found in almost all inorganic compounds of the transition metals, rare earths and actinide elements; it is also found in Cr, Mn, Pt, Pd and rare earth metals and alloys, although the situation is rather more complicated in the case of metals, and the discussion here will be most appropriate to insulators. The principal feature of antiferromagnetism is the spontaneous antiparallel alignment of neighboring electron spins which takes over from the paramagnetic state. The critical temperature of this second-order phase transition is called the Néel temperature (T_N). The strength of the ordering interaction is characterized by the magnitude of T_N which ranges from below 1°K to above room temperature. A few antiferromagnets whose properties have been studied in detail are listed along with their Néel temperatures: NiO, 520°K; Cr₂O₃, 310°K; MnF₂, 67.4°K; CuCl₂·2H₂O, 4.3°K.

The ordering interaction between neighboring metal spins in an insulator is called superexchange since it takes place via an intervening anion, O, F, S, etc. (cf. direct exchange between adjacent ions as encountered in FERROMAGNETISM). Superexchange results from charge transfer (see BOND, CHEMICAL), and it is best illustrated by a typical example, say MnO.

Ground and Excited States of (MnOMn)⁺⁺

In the ground state, the purely ionic configuration, there is no interaction between metal ions. If,

however, one of the two bonding electrons of O⁻ is transferred to the Mn⁺⁺ at left, there will be strong Hund's rule coupling within that ion, and also, the unpaired electron on O⁻ can couple with the Mn⁺⁺ at right. Since the two bonding electrons on O⁻ have opposite spins, the overall interaction will appear as antiparallel exchange coupling between the two Mn ions.

As with ferromagnetism, the magnetic properties of the exchange interaction can be described by assuming an energy in the form

$$\mathcal{H} = \sum J_{ij} S_i \cdot S_j$$

where S_i and S_j are the spin angular momentum vectors of a pair of ions. The dominant exchange constant is between near-neighbor pairs and is negative in sign, so that antiparallel arrangement results. The magnetic structure of an antiferromagnet can be decomposed into two interpenetrating sublattices having oppositely directed magnetizations, M^+ and M^- . The exchange interaction can then be simply represented in terms of the sublattice magnetizations by defining an exchange field proportional to the sublattice magnetization and acting on one sublattice in a direction opposite that of the other:

$$H_E^+ = -\lambda M^-$$

The exchange parameter λ is nearly temperature independent, and the sublattice magnetization grows from zero at T_N to 100 per cent aligned at low temperatures in exactly the same way that the saturation magnetization of a ferromagnet behaves below T_c . Also like ferromagnetism, spin wave theory describes low-lying fluctuations from alignment.

While the exchange interaction produces antiparallel alignment of the spins, their direction with respect to the crystalline axes is a consequence of the magnetic anisotropy, the energetic inequivalence of direction. There are three origins of anisotropy: (1) dipole-dipole interaction among the array of atomic moments which gives anisotropy in all but cubic symmetry; (2) Stark-effect interaction of each single ion with the local crystalline electric fields; and (3) anisotropic exchange, a result of spin-orbit coupling and isotropic superexchange between excited orbital states. The latter two mechanisms are important for non-S-state ions, especially in crystals of low symmetry. The anisotropy energy, $K(\alpha, \beta, \gamma)$, is expressed as a function of the direction cosines of the sublattice magnetizations. When the sublattice is close to the equilibrium direction, called the easy axis, an effective field along the easy axis called the anisotropy field, H_A^+ , is defined in such a way as to produce the appropriate restoring torque on M^+ for small deviations from the easy axis.

The vector model, which uses exchange and anisotropy fields, is very useful in explaining the major experimental features of antiferromagnetism. It is used in Fig. 1(a) to calculate the perpendicular static susceptibility of a typical antiferromagnet, which is shown in Fig. 1(b). At

absolute zero, the susceptibility parallel to the easy axis is zero, since no spin is able to turn over against the exchange field; thermal fluctuations permit an increasing susceptibility with increasing temperature. The dynamic susceptibility may also be derived from the vector model by writing

FIG. 1. (a) The vector model of a simple antiferromagnet is used to calculate the susceptibility to an applied field perpendicular to the easy axis. (b) The susceptibility of a typical antiferromagnet. X_D is the spherical average of the parallel and perpendicular susceptibilities that is observed in a powder specimen.

the Bloch equations for both sublattices, including the approximate effective fields. Antiferromagnetic resonance occurs at a frequency $\omega \approx \gamma \sqrt{2H_E H_A}$ where γ is the electron gyro-magnetic ratio, 2.8 Mc/oersted. Antiferromagnetic resonance has been observed in several materials, often being found at submillimeter wavelengths. In addition to static susceptibility and antiferromagnetic resonance, the principal experiments in antiferromagnetism have been neutron diffraction, which yields the spin structure and sublattice magnetization and sometimes even more details, and nuclear magnetic resonance, which yields high-precision measurements of the sublattice magnetization and insight into the details of charge distributions around ions.

ANTIPARTICLES

One of the great discoveries of modern physics is that for every one of the elementary entities of matter and radiation—"particle"—there exists a corresponding entity—"antiparticle"—with certain of the particle-defining properties identical and others reversed in sign. The properties identical for particle and antiparticle are those determined by space-time symmetry: spin s , mass m , and lifetime τ . Those which are reversed are the internal-symmetry properties: electric charge Q , baryon charge B , light or heavy lepton charge l or L . In contrast with mass and spin, the internal symmetry properties have values which are simply additive in a composite system, and which are conserved in any process; their sign reversal for antiparticles is therefore essential to maintaining the conservation law in the dramatic processes of *pair creation* and *pair annihilation* in which antiparticles are observed appearing and disappearing with their conjugate particles. Also opposite for particle and antiparticle is the approximately conserved internal symmetry property hypercharge Y (the sum of the algebraically largest and algebraically smallest of the electric charges in the mass multiplet to which the particle belongs). Only those particles for which the values of all internal properties are zero, e.g., the photon and the neutral pion, are identical with their antiparticles (see CONSERVATION LAWS AND SYMMETRY).

The progressive recognition of the existence of antiparticles was initiated by Dirac's relativistic anti-electron theory in 1931 and by Anderson's independent experimental discovery of the anti-electron (positron) in 1932. An enumeration of known particles and antiparticles up to 1964 will be found under ELEMENTARY PARTICLES. Here we limit ourselves to a brief account of the theory, particularly of the particle-antiparticle conjugation operator C . This conjugation operator is known to be a symmetry (invariance) operator not only for the energy-momentum (and therefore mass) of free stable particles, but also for the total energy-momentum of a system of particles interacting according to strong or electromagnetic interactions (C invariance). In weak interactions (e.g., non-electromagnetic radioactive decay), it has been found that C invariance by itself does not hold, nor does space-inversion symmetry; only the product of the two (CP invariance) holds approximately. Recent experiments show a small nonvanishing probability for decay of the second type neutral kaon into two pions; this points to a

slight violation also of CP invariance in hypercharge-changing weak interactions.

The best (though not completely adequate) theory that we have of elementary particles and antiparticles is *relativistic quantum field theory*. "Relativistic" means that we require the space-time symmetry of *special relativity*. The representation theory of the relativity group prescribes the characterizing properties of spin and mass. However, while the specific range of observed spin values (all half-integral multiples of a fundamental unit) is explained, the specific range of observed masses is as yet not fundamentally interpreted.

Besides the requirements of relativity, the theory is a QUANTUM THEORY in that it recognizes that the particle-characterizing properties listed above—and related *state-characterizing properties* such as energy-momentum P and angular momentum J —are not all mutually "sharp" or "compatible" observables; compatible observables are such as exhibit in a given system in appropriate states, a characteristic definite value ("quantum number") upon consecutive repeated measurements in any order. A complete set of compatible observables (C.S.C.O.) is any set needed to define the states uniquely, and the individual state is labeled by the set of values which the C.S.C.O. takes on for it. The states are represented as vectors (more exactly "rays") in a Hilbert space and the observables as linear operators. Compatibility (noncompatibility) of two observables is represented by commutativity (noncommutativity) of the corresponding two operators for which we use the same symbols as for the observables. For instance we have:

$$Cm = mC = 0 \quad (CQ = QC \neq 0) \quad (1)$$

In many instances two such operators anticommute, and this is how quantum theory describes the reversals of sign of certain properties under C as indicated above. Thus we have

$$\begin{aligned} CQ + QC = 0 \quad \text{or} \quad CQC^{-1} = -Q \\ CB + BC = 0 \quad \text{or} \quad CBC^{-1} = -B, \text{ etc.} \end{aligned} \quad (2)$$

where the similarity transformation on the left of the second equation on each line represents the effect of particle conjugation on the corresponding charge operator.

To derive these commutation and anticommutation relations for composite systems when they are given for individual particles (by postulate—in accord with the indications of experiment!), and also to describe the relations between reactions in which particles and antiparticles are respectively involved, we adopt the postulates of Quantum Field Theory. This theory, necessarily a many-particle theory, is best described at first for the non-interacting case when we can take the basic states to be n -particle states, n having all possible values. A specific n -particle state $|n_1, n_2, n_3, \dots\rangle$ is characterized by the set of *occupation numbers* n_1, n_2, \dots ($n_1 + n_2 + \dots = n$) specifying the numbers of particles having quantum numbers q_1, q_2, q_3, \dots corresponding to a

(C.S.C.O.): Q_1, Q_2, Q_3, \dots . The state $|0, \dots, 0, \dots\rangle \equiv |\Omega\rangle$ with all $n_i = 0$ is called the *vacuum state*. As in any vector space, there is also the *zero vector* 0. The single-step destruction operator a_λ for particles, and creation operator b_λ^+ for antiparticles associated with the λ th quantum number are introduced in the usual way (see FIELD THEORY) such that they satisfy the standard commutation (anticommutation) rules if the particles satisfy Einstein-Bose (Fermi-Dirac) statistics. One then introduces the *field operator*, which is a linear expansion in the a_λ and b_λ^+ (all λ), and which formally satisfies certain field equations, the latter usually being chosen on the basis of a classical analogy or on the basis of relativistic covariance and general agreement with experiment. All of the consequences of interest then follow from the definition of the field operator and from that of the particle conjugation operator:

$$\begin{aligned} Ca_\lambda C^{-1} &= \eta_c a_\lambda & Ca_\lambda^+ C^{-1} &= \eta_c^* b_\lambda^+ \\ Cb_\lambda C^{-1} &= \eta_c b_\lambda^+ & Cb_\lambda^+ C^{-1} &= \eta_c^* a_\lambda \end{aligned} \quad (3)$$

In Eq. (3) η_c is a phase constant ($|\eta_c| = 1$) which is nonmeasurable and can be chosen ± 1 by convention. If particle and antiparticle are identical—as is true for the photon and neutral pion alone among the "elementary particles" (but also true for certain composites like the singlet positronium when considered as a "particle")—then $b_\lambda = a_\lambda$, and η_c becomes measurable and equal to ± 1 , two physically distinct cases.

For a specific theory, particularly if it is given in Lagrangian form (in which case each of the observables listed above is defined by a symmetry operation on the Lagrangian), these observables can be written as bilinear functionals in the field operators.

As an example, we consider the case of a scalar (spin zero) charged field $\Phi(x)$ associated with a mass m , and satisfying the Klein-Gordon equation

$$(\square + m^2)\Phi(x) = 0 \quad (4)$$

For the C.S.C.O. we choose the linear momentum and the (not-independent) energy. Denoting the destruction operator for the particle of momentum k and energy $k_0 = \sqrt{k^2 + m^2}$ by a_k , and the creation operator for the corresponding antiparticle by b_k^+ , the field operator is given by

$$\Phi(x) = \frac{1}{\sqrt{2(2\pi)^3}} \int \frac{d^3k}{k_0} (a_k e^{-ikx} + b_k^+ e^{ikx}) \quad (5)$$

An explicit representation for C is

$$C = \exp \left[\frac{\pi i}{2} \sum_k (a_k^+ \eta_c^* b_k^+)(a_k - \eta_c b_k) \right] \quad (6)$$

and for the total energy-momentum operator, obtained for instance from the Lagrangian for Eq. (4), we have

$$P_\mu = \int \frac{d^3k}{k_0} k_\mu (a_k^+ a_k + b_k^+ b_k) \quad (7)$$

It is now possible by direct calculation to establish whether P_μ (or any other observable) commutes or anticommutes with C . In this way we can derive for all the free physical fields which have been considered applicable to nature, the results stated earlier in this article concerning preservation and reversal of signs of the fundamental quantum numbers.

It is possible in a similar way to examine the validity of invariance under particle conjugation of the interactions between fields. For instance, the electromagnetic interaction between the electron-field current j_μ and the photon-field potential A_μ is $j_\mu A_\mu$. The two results found for the separate fields by the methods described in the foregoing,

$$Cj_\mu C^{-1} = -j_\mu \quad CA_\mu C^{-1} = A_\mu$$

then guarantee that

$$Cj_\mu A_\mu C^{-1} = j_\mu A_\mu$$

Similarly, C -invariance holds for the accepted forms of strong interactions.

C -invariance does not hold for the V - A (polar vector minus axial vector) four-fermion type of weak interaction occurring, for example, in β -radioactivity. It has been shown however that for quite general interactions with proper orthochronous space-time symmetry, provided they are local, there is automatically invariance under the combined operation CPT where T represents time inversion (CPT Theorem). "Proper orthochronous" space-time symmetry of the interactions means that they are invariant under rotations, translations in space and time, and shifts to uniformly moving frames: "locality" means that the interactions consist of a linear combination of products of the fields and finite-order derivatives of the fields. Equality of mass and lifetime, anti-equality of charge and magnetic moment, and (with certain restrictions) conjugacy of decay schemes for a particle and its antiparticle all follow from CPT invariance alone. And this rests only on proper space-time symmetry, general principles of quantum theory, and the locality requirement.

ARCHITECTURAL ACOUSTICS

Although the practice of architectural acoustics involves a wide variety of special problems and techniques, the basic reasons for acoustical design are simply,

- (a) to provide a satisfactory acoustical environment, not too noisy and often not too quiet, for people at work and relaxation;
- (b) to provide good hearing conditions for speech; and
- (c) to provide a pleasant acoustical environment for listening to music.

Designing for Satisfactory Acoustical Environment. Each acoustical situation must be treated as a system comprised of three parts: source, transmission path, and listener. When the properties of the source are known, the transmission path can be modified to attenuate the sound to suit the listener's needs.

Sources. Noise sources are specified in terms of the total acoustical power radiated in each of a number (generally between 8 and 25) of contiguous frequency bands.^{1,2} A standard set of ten bands is listed in Table 1.

TABLE 1. STANDARD OCTAVE FREQUENCY BANDS

Lower and Upper Frequency Limits of Each Band (cps)	Geometric Mean Frequency of Each Band (cps)
22.1-44.2	31.5
44.2-88.5	63
88.5-177	125
177-354	250
354-707	500
707-1,414	1,000
1,414-2,828	2,000
2,828-5,655	4,000
5,655-11,310	8,000
11,310-22,620	16,000

Because of the wide range of sound powers encountered in practice, it is customary to express them in a logarithmic form. Thus we speak of the strength of a sound source in terms of *sound power level*, W , in decibels, defined by item 1 in Table 2.

TABLE 2

Decibel Scale	Abbreviation	Reference Quantity	Definition
Sound power level	PWL	$W_{\text{ref}} = 10^{-12}$ watt	$10 \log_{10} \frac{W}{W_{\text{ref}}}$ db
Sound intensity level	IL	$I_{\text{ref}} = 10^{-12}$ watt/m ² $= 10^{-14}$ watt/cm ²	$10 \log_{10} \frac{I}{I_{\text{ref}}}$ db
Sound pressure level	SPL	$p_{\text{ref}} = 0.00002$ newton/m ² $= 0.0002$ microbar	$10 \log_{10} \frac{p^2}{p_{\text{ref}}^2}$ $= 20 \log_{10} \frac{p}{p_{\text{ref}}}$ db

We note that sound power W is expressed in watts.

A listener does not experience the total sound power from a source, since it radiates in all directions, but rather the proportion that arrives at his ear. Thus we speak of *sound intensity*, I , as the sound power passing through a small area at the point of observation. The units are watts per square centimeter or per square meter. *Sound intensity level*, IL, in decibels, is defined by Item 2 in Table 2.

There is no commercially available instrument for measuring sound intensity, so it must be determined indirectly from the mean-square sound pressure, p^2 , i.e., the time average of the square of the instantaneous sound pressure in the acoustic wave. This quantity can be determined readily with a pressure microphone. The relation is given by,

$$I \approx p^2 / \rho c \text{ watts/m}^2 \quad (1)$$

where, ρ is the density of air (or other gas) in kilograms per cubic meter and c is the speed of sound in air in meters per second. *Sound pressure level*, SPL, in decibels, is defined by item 3 in Table 2.

Instruments and techniques for the measurement of sound pressure levels are widely available.² Typical measured values of sound power levels for many sources are given in references 1 to 3.

Paths. Sound may travel from a source to a receiver by many paths, some in the air (outdoors or in a room), some through walls and some along solid structures. In the latter two cases, the sound is radiated into the air from the vibrations of the surfaces.

Outdoors, the relation between the sound pressure level measured at distance r from a source and the sound power level of the source is given by,

$$\text{SPL}_\theta \approx \text{PWL} + \text{DI}_\theta - 20 \log_{10} r - 11 \text{ db} \quad (2)$$

where it is assumed that the source is near a hard-ground plane at a distance r in meters from the receiver (also near the plane) and that the source produces different sound intensities in different

directions, θ , as described by a *directivity index*, DI_θ (see reference 2). If the source radiates sound equally in all directions, then $\text{DI} = 0$. In practice, sources generally have directivity indexes in the range of 0 to 12 db in the direction of maximum radiation. At large distances, r , there will be losses in the air itself at frequencies above 1500 cps. Also, wind, temperature gradients, and air turbulence may reduce or augment the SPL_θ determined from Eq. (2).

In a room, the sound pressure level produced by a nondirective source is given by,

$$\text{SPL} = \text{PWL} + 10 \log_{10} \left(\frac{1}{4\pi r^2} + \frac{4}{R} \right) \text{ db} \quad (3)$$

where r is the distance between the receiver and the microphone and R is the *room constant* in square meters (see reference 2). Typical values of R are found in Fig. 1.

In practical cases, we are often interested in the sound pressure level produced in a room separated by a partition (wall) from the room in which the source is located. We assign a *transmission loss*, TL, in decibels to the intervening wall. Curves of transmission loss versus frequency for several different building structures are given in Fig. 2 and reference 4. The equation relating SPL to the PWL of the source is,

$$\begin{aligned} \text{SPL}_2 = \text{PWL}_1 - \text{TL} + 10 \log_{10} \left(\frac{S_w}{R_1} \right) \\ + 10 \log_{10} \left(\frac{1}{S_w} + \frac{4}{R_2} \right) \text{ db} \end{aligned} \quad (4)$$

where SPL_2 is the sound pressure level in the second room produced by a source in the first room; TL is the transmission loss; S_w is the area of the wall in square meters, and R_1 and R_2 are the room constants for the first and second rooms, respectively, in square meters. It is assumed that the sound pressure level is measured near the common wall; in the center of the room it may be 3 to 5 decibels lower.

Technique. It is apparent from Eq. (4) that the techniques for noise reduction indoors are threefold. First, make every effort to reduce the

FIG. 1. Approximate value of room constant R for five categories of rooms ranging from "live" to "dead." Metric units referenced at bottom and left, English units top and right. The Greek letter $\bar{\alpha}$ indicates the percentage of the energy that is removed from a sound wave when it reflects from an "average" surface of the room. It is called the average sound absorption coefficient.

FIG. 2. Transmission loss, TL, of six typical building structures.

sound power radiated by the source, i.e., use quiet ventilating fans, quiet typewriters, quiet factory machinery, and so forth. Enclose noisy machinery in separate rooms or in enclosures. Mount vibrating machinery on resilient pads or springs. Second, provide walls with suitably high transmission losses between rooms. For example,

between adjoining apartments, walls 4 to 6 of Fig. 2 are usually satisfactory, while walls 1 to 3 are not. On the other hand, walls 2 and 3 would be satisfactory between rooms of the same apartment, while wall 1 would not. Finally, increase the room constants by adding sound-absorbing materials to either or both rooms, e.g.,

carpets and draperies, or acoustical materials on ceiling or walls or both. The sound-absorbing efficiencies of various materials are given in references 2, 3 and 5.

It is of great importance to observe that when a wall is placed between two rooms or when an enclosure is built around a noisy machine, the structure must be hermetically sealed, or, if air-flow is necessary, it must be conducted in and out of the enclosure through suitable silencers. A hole even as small in diameter as a pencil can render an otherwise satisfactory wall or enclosure inadequate acoustically.

In cases of very high noise levels where it is impractical acoustically to quiet or to isolate the machine, then ear plugs, ear cushions, or both, must be worn by personnel exposed to the noise.

Criteria for Design. Acceptable noise levels in rooms of various types in each of eight octave frequency bands are shown by Fig. 3 and Table 3.

Auditoriums for Speech. Three goals must be met in the design of auditoriums for speech. First, the ambient noise levels must be sufficiently low (see Table 3). Second, speech must be loud enough in all parts of the room so that faint syllables can be heard in the presence of normal audience noise. This second goal is achieved in small auditoriums (under about 500 seats) by proper shaping of the front part of the hall so that the speaker's voice is directed uniformly to

FIG. 3 Noise Criteria (NC) curves for various types of building spaces given in Table 3. Measurements are made with an octave band filter and the readings in each band should not exceed that shown on the appropriate NC curve.

TABLE 3

	Recommended NC Curve*	Communication Environment	Typical Applications
Office	30-35	"Quiet" office; satisfactory for conferences at a 15-ft table; normal voice 10-30 ft; telephone use satisfactory	Private or semi-private offices, reception rooms and small conference rooms for 20
Office	40-50	Satisfactory for conferences at a 4- to 5-ft table; telephone use occasionally slightly difficult; normal voice 3-6 ft; raised voice 6-12 ft	Large engineering and drafting rooms, etc
Office	50-55	Unsatisfactory for conferences of more than two or three people; telephone use slightly difficult; normal voice 1-2 ft; raised voice 3-6 ft	Secretarial areas (typing), accounting areas (business machines), blueprint rooms, etc.
Hall for music	15-20	All types of music	Concert halls, music rooms, broadcast studios and opera houses
Auditorium (less than 500 seats, no amplification)	20-25	Lectures with raised voice	Business, school, and hotel auditoriums
Schoolroom (no amplification)	25	Normal voice from standing or sitting position	Grammar schools, high schools, and universities
Church (no amplification)	25	Sermon from lectern	Small churches and synagogues
Apartment or hotel	25-30	Listening to TV, using telephone, and conversation	Living and sleeping areas

* NC = Noise criteria, see Fig. 3.

all parts of the hall. In large halls (over 500 seats), electronic amplification of speech is usually necessary. Third, the reverberation in the auditorium should be sufficiently low that speech is distinct. In auditoriums where there is no sound system, this requirement means that either the ceiling should have an average height of less than 30 feet above the main floor, assuming that the seats are upholstered and that there are no large floor areas without seats. If the ceiling height is over 30 feet, sound-absorbing materials will have to be added to the walls and, perhaps, the rear ceiling to control the reverberation. A satisfactory shape of a 500-seat auditorium for unamplified speech is shown in Fig. 4.

Fig. 4. Satisfactory ceiling shape for a speech auditorium with less than 500 seats.

Auditoriums for Music. There appears to be no single, ideal architectural solution for the acoustical design of a hall for music. Successful acoustics have been achieved with rectangular, fan or wedge, horseshoe, and even asymmetrical, plans. But though this is true, the many attributes of musical-architectural acoustics are so closely interrelated that if a hall is to be successful, the architect must solve all requirements simultaneously.

The music of each era of the past was composed for a different acoustical environment. Music of the Baroque period (Bach and earlier), except for organ music, was composed for small halls with relatively short reverberation times. (That is to say, a loud sound should take about 1.5 seconds to die down to inaudibility after its source is cut off abruptly. This quantity, called *mid-frequency reverberation time*, is measured with full audience present at 500 and 1000 cps and averaged.) Music of the Classical period (early Beethoven, Mozart and Haydn) was composed for larger halls with medium reverberation times (about 1.7 seconds). On the other hand, music of the Romantic period (after 1850) was, in general, composed for fairly large halls with long reverberation times (about 2.2 seconds). Today, halls must not only accommodate a musical repertoire extending over centuries, but often they must seat so large an audience that they become an entirely new type of space in which to perform music.

In the development of the design of a hall, the acoustics dictate the cubic volume and strongly influence the orientation of every sound-reflecting surface, the interior materials, and even the seating.

Concert hall and opera house design is complex,^{6,7} but some guiding principles stand out. The seating capacity should be low, below 2200 if possible. The ceiling should have an average height of 45 feet, if there are no balconies, or 55 feet with balconies, measured above the floor beneath the main floor seats. The hall should be narrow, or other means such as suspended panels should be provided for producing early sound reflections at listener's positions. Finishes for the interior should primarily be plaster. Not over 20 per cent should be wooden if the strength of the bass tone is to be preserved. Irregularities on all the surfaces should be provided to produce diffusion and blending of the sound. Above all, avoid echo, noise and tonal distortion. Finally, the orchestra enclosure should provide sectional balance in the orchestra and permit the musicians to hear each other.

Boston Symphony Hall, one of the world's best-liked concert halls, is rectangular, as shown in Fig. 5, and meets the general requirements

BOSTON, SYMPHONY HALL

FIG. 5. Drawings of Symphony Hall, Boston, Mass.

listed above. Its mid-frequency reverberation time, with full audience, is 1.8 seconds.

ASTRODYNAMICS

Astro dynamics is the study of how bodies move in space, particularly under "free fall," or the influence of gravitational forces alone, but also as influenced by nongravitational forces such as drag, thrust, electromagnetic forces, and corpuscular radiation. The science of astrodynamics is a modern application of classical celestial mechanics to space flight. Behavior of the body in a single central gravitational force field (Keplerian flight) will be treated first, and asphericity, n -bodies, and nongravitational forces will be considered as perturbations. Atmospheric aerodynamics is not included (see AERODYNAMICS).

Ballistic Trajectories. When a projectile is fired in a vacuum from the flat earth, its trajectory after leaving the gun barrel is determined by the momentum due to the initial velocity vector and the acceleration due to the gravity vector. As shown in Fig. 1, the horizontal component of

FIG. 1. Ballistic trajectory over a flat earth.

velocity remains constant until impact, while the vertical component of velocity is summed algebraically with the time integral of the acceleration due to gravity. If the vertical component of velocity is high enough, the projectile will travel so far that the flat earth assumption is not valid because the gravity vector rotates as the horizontal distance increases. In this case, the trajectory is seen to become an ellipse (Fig. 2) with the center of mass of the earth at one focus.

The range of a ballistic missile is a function of initial or burnout velocity and the elevation angle. As the burnout velocity is increased, the missile will travel farther before impact. At one critical velocity vector (25,900 ft/sec at zero-degree elevation angle), the projectile will not fall fast enough to hit the earth, but (neglecting atmospheric braking) would circle it. At this velocity, the centrifugal force exactly equals the mass attraction of the earth.

FIG. 2. Ballistic trajectory over a spherical earth.

Orbital Energy. The kinetic energy of a moving mass (m) with velocity (V) is

$$E_k = \frac{1}{2}mV^2$$

The potential energy, referenced to zero energy at an infinite distance from the attracting mass (and becoming more negative as it approaches the attracting mass), is

$$E_p = \frac{-mMG}{r}$$

where $MG = K = g_0 r_0^2$ is the gravitational constant for the attracting mass and r is the distance between the masses.

For the earth (used in satellite calculations):

$$K \approx 1.407 (10^{16}) \text{ ft}^3/\text{sec}^2$$

For the sun (used in planet and solar system travel calculations):

$$K \approx 4.679 (10^{21}) \text{ ft}^3/\text{sec}^2$$

For the moon (used in lunar orbit calculations):

$$K \approx 1.727 (10^{14}) \text{ ft}^3/\text{sec}^2$$

The total energy per unit mass, then, is

$$\frac{E}{m} = \frac{1}{2}V^2 - \frac{K}{r}$$

In a ballistic flight after power cutoff and before reentry, the total energy of a vehicle remains constant.

It was observed by early astronomers, and can be verified by integrating the equations of motion of a particle in space, that the total energy per unit mass is related to the semimajor axis a of the conic Keplerian trajectory

$$\frac{E}{m} = \frac{-2K}{a}$$

This is reduced to the famous and very useful *vis viva* energy equation:

$$V^2 - \frac{2K}{r} = \frac{-K}{a} \quad (1)$$

which is constant for any given trajectory.

This discloses the interesting fact that the semimajor axis of the orbital ellipse (a) is determined by the velocity and radius at the injection

point, or for that matter, at any instant during orbital flight. It is

$$E = -\frac{K}{a} = \frac{1}{2}V^2 - \frac{2K}{r}$$

The energy constant ($-K/a$) is also called C_a energy in the literature. It is a very important parameter:

(1) It is a measure of the total energy of an orbit (and therefore is useful in comparing orbits).

(2) It defines the size of an orbit.

(3) Given the periapsis distance (the distance at closest approach), it defines the shape of an orbit.

From the *vis viva* equation, the velocity required for circular orbit (where $a = r = r_0 + h$) at an altitude h above the earth is found to be

$$V_c = \sqrt{\frac{K}{r_0 + h}}$$

and the period is

$$P = \frac{2\pi(r_0 + h)}{V_c} = 2\pi\sqrt{\frac{(r_0 + h)^3}{K}}$$

The theoretical minimum orbit period of an earth satellite (at treetop height, neglecting air drag) is when $h = 0$ and the period is

$$P = 2\pi\sqrt{\frac{r_0}{g_0}} \approx 84.5 \text{ minutes}$$

Notice that the velocity and the period are both dependent on the gravitational attraction and the altitude. The mass of the vehicle is not a factor as long as it is negligible compared with the attracting mass.

Also, as will be shown shortly, the *vis viva* integral is a measure of the hyperbolic excess velocity—the residual velocity of a vehicle after it has left the field of the attracting mass. Notice that so far, both the orbital characteristics and the orbital energy are referenced to a particular attracting mass, and the center of mass attraction always lies on the plane of the trajectory and at the focus. Notice also that in central force field theory, the radius of the earth has no significance except in establishing the launch point and the point of impact. In addition, the fact that the launch point is rotating in space merely establishes an initial velocity vector before launching the vehicle. For this reason, it requires less energy to reach circular orbit velocity to the east than to the west. Of course, some orbital information may be given in terms of altitude which is simply the instantaneous radius minus the earth's radius.

Cotangential Orbits. If the injection velocity is greater or less than the circular velocity for that injection altitude, or if the injection angle is not zero, the orbit will not be circular. It can be

shown that the most efficient injection angle for satellite or space flight orbits is near zero.

For injection angles of zero degrees, if the velocity is less than the circular velocity, the orbit will be a subcircular ellipse with the injection point the farthest point from the center of mass attraction (focus) or apoapsis. If the injection velocity exceeds the circular velocity but is less than $V_c\sqrt{2}$, the orbit will be a hypercircular ellipse, with the injection point the nearest or periapsis point. These cotangential orbits are shown in Fig. 3. If the injection angle is not zero

FIG. 3. Cotangential orbits.

degrees, the orbit is not a circle and the injection point is neither the apoapsis nor the periapsis.

Criterion for Escape. The kinetic energy exactly equals the potential energy when

$$\frac{1}{2}V^2 = \frac{2K}{r}$$

or

$$V = \sqrt{2K/r} = V_c\sqrt{2}$$

Therefore, if the injection velocity V_0 equals $\sqrt{2}$ times the circular velocity, the vehicle has just enough kinetic energy to overcome the potential energy of mass attraction, and it escapes from the earth or other attracting mass, theoretically reaching zero velocity at infinite distance from the center of mass attraction (assuming the vehicle is influenced by the gravity of only one body).

For $V_0 = V_c\sqrt{2}$, the trajectory is parabolic. For $V_0 > V_c\sqrt{2}$, the trajectory is hyperbolic. These trajectories are all in the family of curves called "conics"—the circle, ellipse, parabola, and hyperbola (and the trivial cases of the line and the point).

Notice that each of the closed orbits passes through its own injection point in space. The point will not generally be the same point over the earth due to the earth's rotation. Notice also that since the velocity vector and the position vector at any point on the orbit determine the entire trajectory, the orbits are dynamically reversible. Therefore, a vehicle approaching a planet with hyperbolic velocity will, if it does not impact, pass the periapsis and continue outbound on the symmetrical continuation of the approach hyperbola.

The Velocity Asymptote. The residual velocity (at an infinite distance from the attracting mass or hyperbolic excess velocity) is described by the velocity asymptote vector V_∞ which defines the injection requirements and is, therefore, a very useful parameter in describing mission guidance and energy requirements.

The square of the hyperbolic excess velocity is the C_3 energy of the orbit.

$$V_\infty^2 = C_3 = -\frac{K}{a}$$

where the semimajor axis (a) goes negative for hyperbolic flight.

For parabolic trajectories, the direction of the velocity asymptote is 180° from the perigee radius and the C_3 energy is zero. For hyperbolic trajectories, the angle between the velocity asymptote and the perigee radius is less than 180° and is a function of the C_3 energy (Fig. 4).*

FIG. 4. Angle between outward radial (asymptote) and perigee as a function of energy.

Guidance Requirements for Space Flight. Since the laws of astrodynamics describe the flight path under gravitational forces, the function of the guidance system is to guide the vehicle during the thrust period to the required injection altitude and position and velocity vectors, and to cut off the thrust promptly.

The dynamic position of the vehicle in orbit is given by its instantaneous radius vector (r) from the attracting mass and by the true anomaly (η), which is the angle from the periapsis radius to the instantaneous position radius measured at the focus. Two other angles are very useful in relating the position of the vehicle in orbit to time: the eccentric anomaly and the mean anomaly. The eccentric anomaly (E) is the angle measured at the center of the orbit (rather than at the focus) from the periapsis radius to a point on an auxiliary circle which just contains the ellipse, the location of the point being the extension of a line perpendicular to the major axis and passing through the vehicle position. The true anomaly and the eccentric anomaly are shown in Fig. 5.

* Taken from reference 6 by permission.

η = TRUE ANOMALY
 E = ECCENTRIC ANOMALY

FIG. 5. True anomaly and eccentric anomaly.

The mean anomaly (M) is merely the time angle in radians, or the phase of the orbital period. It is given by the equation

$$M = \frac{2\pi}{P}(t - t_0)$$

where P is the orbital period, and $t - t_0$ is the time since last periapsis passage.

Kepler's Equation. The equation relating time to orbital position is given most concisely by Kepler's equation

$$M = E - e \sin E$$

Useful Orbit Relationships. A number of useful equations can be derived based on the relationship of velocity to altitude at any instant for a given attracting mass (K) and orbit size (a). It should be emphasized here that the trajectory curves are loci of the center of mass of the orbiting vehicle and are independent of vehicle attitude. The flight path direction does not describe the pointing direction of the vehicle in free flight.

Some useful orbit equations for the circle, ellipse, parabola, and hyperbola are shown below:

$$(1) \text{ Eccentricity } e = \sqrt{\frac{a^2 - b^2}{a^2}} \quad \begin{array}{l} = 0 \text{ (C)} \\ < 1 \text{ (E)} \\ = 1 \text{ (P)} \\ > 1 \text{ (H)} \end{array}$$

$$(2) \text{ Apoapsis radius } r_a = a(1 + e)$$

$$(3) \text{ Periapsis radius } r_p = a(1 - e)$$

$$(4) \text{ Semimajor axis } a = \frac{-K}{V^2 - 2K/r} = r \text{ (C)} \\ < \infty \text{ (E)} \\ = \infty \text{ (P)} \\ = -\frac{K}{V_\infty^2} \text{ (H)}$$

(5) Orbital energy constant

$$C_3 = -\frac{K}{a} = V^2 - \frac{2K}{r} < 0 \text{ (C, E)}$$

$$= 0 \text{ (P)}$$

$$> V_{\infty}^2 \text{ (H)}$$

(6) Radius

$$r = a(1 - e \cos E)$$

(7) True anomaly η

$$= \cos^{-1} \left(\frac{\cos E - e}{1 - e \cos E} \right) \text{ (E)}$$

(8) Flight path angle θ

$$= \tan^{-1} \frac{e \sin \eta}{1 + e \cos \eta}$$

(9) Velocity

$$V = \sqrt{\frac{2K}{r} - \frac{K}{a}}$$

(10) Periapsis velocity V_p

$$= \sqrt{\frac{K}{r_p} (1 + e)}$$

(11) Apoapsis velocity V_a

$$= \sqrt{\frac{K}{r_a} (1 - e)}$$

Perturbations. Perturbations are the components of acceleration of an object which are not accountable by the simple inverse-square central gravitational force field.

Examples of such perturbations to Keplerian trajectories are:

(1) The mass of the second body is not negligible.

(2) Asphericity of the principal mass (such as the equatorial bulge).

(3) Nongravitational forces—thrust, drag, electromagnetic, radiation.

The Keplerian conics are useful not only for approximations and feasibility studies but as reference orbits from which perturbations may be calculated.

The Twenty-four Hour Orbit. The circular orbit with 19,000-nautical-mile altitude is of interest because its period is 24 hours and so the satellite can be made to hover over one place on the earth.

Hohmann Transfer. Since impulsive velocity increments are more efficient than long continuous thrust to injection, the ascent to the 19,000-mile altitude is made by a low-altitude injection into an elliptical orbit with the desired apogee. At apogee, about 5½ hours flight from injection, a second injection into the circular orbit is made. This transfer is the classical Hohmann ellipse (Fig. 6).

Change of Orbital Plane. The inclination of an orbit to the equator varies with launch azimuth, but the minimum angle of inclination is the latitude of the launch site unless a change of plane is made in flight. A change of plane can be made most efficiently by a thrust applied normal to the orbital plane as the vehicle crosses the equator. If more than one orbit is involved—such as the low altitude parking orbit, the Hohmann transfer, and the high-altitude circular orbit—it can be shown that the ΔV required for change of plane is less at the highest orbit.

Station Keeping. To maintain a desired orbit, 24-hour or otherwise, an occasional small increment of velocity may be required. The velocity

FIG. 6. Hohmann transfer ellipse.

increment to maintain a low-altitude orbit (100 to 200 miles) against the tenuous atmospheric drag is in the order of a few feet per second each week, depending on the ballistic coefficient of the vehicle.

Lunar Flight. The minimum energy flight to the moon would again be a Hohmann transfer, injecting at the perigee and reaching the moon at apogee. However, the minimum energy flight would require a 90-hour flight time. The time can be considerably reduced with relatively little increase in injection velocity. The minimum energy ellipse is very nearly parabolic ($e = 0.97$), requiring a velocity (35 860 ft/sec) very close to escape velocity, so a relatively small increase in velocity will greatly increase the semimajor axis of the ellipse beyond the moon and reduce the flight time to the moon. A flight with an injection velocity of 36 093 ft/sec would reduce the flight time to 66 hours. Instead of being at apogee, the moon would be along one side of the ellipse.

Interplanetary Flight. If planetary orbits were circular and coplanar, the minimum energy flight would be that required to provide the additional velocity to put the spacecraft into a sun-centered Hohmann transfer to Mars, or the retrograde velocity necessary for the spacecraft to fall into the smaller ellipse for a Hohmann transfer to Venus. The minimum energy flight opportunity would be when the earth at launch and the target planet at arrival have a 180° heliocentric central angle.

Synodic Periods. These opportunities occur at synodic periods due to the different orbital periods of the planets. For Mars, the synodic period is 25.6 months; Venus is 19.2 months; and Mercury is 3.8 months.

However, the planetary orbits are not circular, and they are not coplanar (Table 1); therefore, the minimum energy flights are not Hohmann transfers. The best launch dates are still very close to the synodic period (except for Mercury), but the minimum energy required is not the same at each period. Table 2 shows the minimum energy (geocentric), flight time, and planetary distance from the sun at arrival for various launch dates at the synodic period.

TABLE 1. PLANET ORBIT ECCENTRICITY AND INCLINATION TO ECLIPTIC*

Planet	Orbit Eccentricity	Inclination to Ecliptic (degrees)
Earth	0.017	0
Venus	0.007	3.39
Mars	0.093	1.85

The energy required at each synodic period varies with the planet-to-sun distance and the distance from the ecliptic at encounter. These periodic best-launch opportunities usually last from two to five days before serious energy penalties begin.

Summary of Astrodynamical Rules. For Keplerian flight (only one force: a point gravitational attraction):

(1) The minimum velocity required for circular orbit decreases as injection altitude increases.

(2) The period of a closed orbit increases with the mean altitude of the orbit.

(3) The mean velocity of a closed orbit decreases as the mean altitude of the orbit increases.

(4) The escape velocity equals $\sqrt{2}$ times the circular orbit velocity.

(5) Orbits with injection velocity greater than circular velocity but less than escape velocity are ellipses.

(6) Orbits with injection velocity greater than escape velocity are hyperbolas.

(7) The orbital energy (hence semimajor axis, mean velocity, mean altitude, and period) remains constant in Keplerian trajectories. The energy is positive for hyperbolas, zero for parabolic escape, and becomes more negative as the semimajor axis decreases.

(8) The center of mass attraction is at the focus of the conic trajectory.

(9) Multibody trajectories can be approximated by "patched conics"—a series of Keplerian trajectories (earth-centered, sun-centered, planet-centered).

(10) Conic trajectories define the locus of the center of mass under gravitational forces. Vehicle attitude is not defined by the trajectory.

(11) The trajectory is defined by position and velocity vectors at any instant. Hence, guidance is needed only during the thrust periods.

ASTROMETRY

Astrometry deals with the space-time behavior of celestial bodies and therefore belongs to the classical field of astronomical studies. It is often referred to as fundamental, positional or observational astronomy.

Early astrometric investigations were directed mainly toward establishing a suitable frame of reference for the determination of the complex motions of the planets, while the studies of the positions and motions of the individual stars as well as the various stellar systems gradually developed as improved precision of observations made it possible to discover and observe these motions.

The fundamental, and perhaps most difficult, problem of astrometry is the establishment of a reference system against which the motions of the celestial bodies can be measured.

The principal planes involved in the spherical coordinate systems usually used in astrometry are the equator, defined by the rotation of the earth on its axis, and the ecliptic, defined by the revolution of the earth around the sun. The positions of both these planes vary continuously in a most complicated manner due to gravitational forces and couples between earth and the moon, the sun, and the principal planets. Such motions of the reference planes are reflected in the positions of the stars referred to them.

The motions of these planes cannot be derived entirely from theory alone, but must be deduced from observed changes in the positions of the stars which, in turn, are also in motion. This complication has forced the construction of the astronomical coordinate system to proceed by a series of successive approximations which are still in progress. Initially, the sun, and planets were observed against the "fixed stars." From these observations came the first approximations of the motions of the solar system by the laws of dynamics and of the effect of the changing orientation of the earth's axis of rotation (precession) upon the positions of the stars. Successive repetitions of the observational process have gradually improved our knowledge of these and other motions affecting the fundamental planes of the coordinate system, each improvement resulting in an increase in our knowledge of the positions and motions of the stars.

Observational programs for the improvement of the celestial coordinate system are long and tedious and must be conducted with meticulous care. They make use of highly developed instruments and observing techniques which, in combination with adopted theories of the rotation of the earth and its motion around the sun, enable the positions of the equator and equinox to be derived anew and the positions of the stars to be related to them. Each such program is an independent effort to reconstruct the celestial coordinate system. Meridian circles have generally been used for this kind of work. The results of such programs are said to be fundamental and

are usually published in the form of star catalogs.

From time to time, when sufficient fundamentally observed catalogues have accumulated, they are combined with similar earlier material to form a *Fundamental Star Catalog*. This catalog is usually regarded as the best representation that may be had of the celestial coordinate system at the time of its publication; the right ascensions and declinations of the stars in the catalog define the system for the equinox and epoch chosen for the catalog. The proper motions in combination with the adopted values of the constant of precession permit the system to be referred to equinoxes and equators at other epochs.

The latest and most precise of the fundamental catalogs is designated the *FK4* and was published by the Astronomischen Rechen-Institut, Heidelberg, Germany in 1963. The catalog contains the positions (right ascension and declination) and the changes with time (precession and proper motion) of 1535 stars. These data were compiled from nearly 200 star catalogs containing observations over a span of 110 years. Two other fundamental catalogs that have been extensively used are the *GC*, *Albany General Catalogue of 33342 Stars* and the *N30, Catalog of 5268 Stars*.

The coordinate system provided by the positions and motions of the stars in a fundamental catalog serves as a reference system for the measurement of other star positions and proper motions which must be carried out for a variety of problems originating in the study of stellar motions, in geodesy, in the determination of time, in space research and others.

With the exception of the *GC*, which contains all the stars brighter than the 7th magnitude, fundamental catalogs do not contain a complete list of all stars down to a certain magnitude as, for example, the survey catalogs do. The prototype of the survey catalogs for star positions is the *Bonner Durchmusterung* which contains the positions of 320,000 stars to a limiting magnitude of 9.5 and north of declination -2° . Although the observations for the catalog were made in the middle of the past century, the catalog and the charts made from it have been an extremely useful tool for astronomers for identification of star fields. The survey was later extended to the south celestial pole by the Bonn, Cape and Cordoba Observatories.

Positions of the fainter stars on a fundamental system are obtained by a close coordination between visual and photographic programs. The positions of a selected number of moderately bright stars (7th to 9th magnitude) are related to the fundamental system by meridian circle observations. These stars are then used as a position reference for the photographic observations of the fainter stars, thus tying them to the fundamental system.

An example of this procedure is the large astrometric project initiated toward the end of the nineteenth century and carried out by international cooperation.

The fundamental system adopted for this undertaking was embodied in the *FC (Fundamental-Catalog für die Zonen-Beobachtungen am Nördlichen Himmel)* developed by Auwers. The visual program, designated the *AGK (Astronomische Gesellschaft Katalog)*, was carried out through the collaboration of 12 northern hemisphere observatories and resulted in the determination of the positions with respect to the *FC* of 144,128 stars to the limiting magnitude of 9 and north of -2° declination. The extension of the visual work into the southern skies was gradually carried out by other observatories. The adjunct photographic program, known as the *Carte du Ciel* or the *Astrographic Catalogue* called for observations down to approximately the 11th magnitude covering the entire sky by $2^\circ \times 2^\circ$ fields. Originating in 1887, the program has only recently been completed and involved the participation of 18 different observatories. The positions in the catalogs are given in the form of rectangular coordinates as measured on the plates, but by means of auxiliary tables, these coordinates can be translated into right ascension and declination. Each field was photographed a second time with a longer exposure with a limiting magnitude of 14 to be used for the purpose of star charts.

Several other catalogs of photographically derived positions have been published. Among the catalogs of this nature may be mentioned the *AGK2 (Zweiter Katalog der Astronomischen Gesellschaft)* and the Yale and Cape photographic catalogs.

The *AGK2* was rigorously related to the fundamental system represented by the *FK3 (Dritter Fundamentalkatalog des Berliner Astronomischen Jahrbuchs)* through the use of simultaneous visual observations of about 13,000 moderately bright stars in making the plate reductions. The *AGK2* plates were taken at the Bonn and Bergedorf Observatories and covered the sky in $5^\circ \times 5^\circ$ overlapping fields from 2° to the north pole. The resulting catalog contains the positions of over 180,000 stars for the mean epoch of 1930. A second photographic series of observations of these stars, known as the *AGK3*, has been in progress at the Bergedorf Observatory since 1956. The plates will be reduced to the system of the *FK4* by use of the positions of some 21,000 reference stars observed simultaneously through an international cooperative program involving 12 meridian circles in the northern hemisphere. A comparison of the plate results at the two epochs will give rather accurate proper motions with respect to the fundamental system for the entire 180,000 stars. The majority of these stars are brighter than the 9th magnitude. A good many, however, are as faint as the 11.5 photographic magnitude.

Except for a gap between $+50^\circ$ and $+30^\circ$ declination, the Yale photographic catalogs cover the sky from $+90^\circ$ to -30° while the Cape catalogs, at present, extend this coverage to -64° declination. Cape photographic catalogs in preparation will complete the coverage to the

south pole. Both series of catalogs were taken by zones of declination by use of wide-angle cameras (from $5^\circ \times 5^\circ$ to $10^\circ \times 14^\circ$) and were reduced to a fundamental system (not always the same one) by use of contemporary meridian circle observations. The mean epochs of the positions in these catalogs range from the early 1930's to the late 1940's. The stars in these catalogs are similar in magnitude range to those in the *AGK2* and *AGK3*. Both the Yale and Cape Observatories now have plans in progress to reobserve all the stars south of the equator by photographic methods. The visual observations of about 20,000 stars needed to tie the photographic results to the fundamental system are being obtained through an international cooperative program known as the *SRS (Southern Reference Star Program)*. It is planned eventually to derive proper motions for all the stars in these catalogs through a comparison of the current photographic positions with the earlier ones.

An important source for obtaining proper motions of the fainter stars is a combination of early photographic plates with recent ones taken with the same telescope. The proper motions derived in this way are relative proper motions and require further reductions for transformation into absolute proper motions in a fundamental system. This procedure has been followed in several extensive programs aimed at solving such problems as determining the solar motion, and deriving secular parallaxes and galactic rotation.

Proper motions for tens of thousands of stars have been obtained by this method while radial velocities for a lesser number of stars have been determined from the spectroscopic application of the Doppler principle. Besides the proper motion and radial velocity, the distance of a star is needed to determine its motion in space. For stars beyond 30 parsecs from the solar system it becomes increasingly difficult to obtain all three factors involved, and often knowledge of stellar motion is either based on proper motions or radial velocities alone. However, by various statistical devices substantial information about stellar motions has been obtained.

On the basis of these studies, the sun's velocity has been determined to be about 20 km/sec towards a point in space not far from Vega, although the amount and direction of the motion varies depending upon the chosen group of stars.

As a result of the sun's motion through space, the stars show a parallactic or secular shift which can be used to determine their distances. Because of the individual motions of the stars, this method is applicable only to groups of stars with the assumption that their individual motions are random. By means of the secular parallax method, general ideas of the distances of stars up to 1000 parsecs have been obtained.

From statistical studies of proper motions and radial velocities, it was found in 1927 that the stars in our galaxy are moving in orbits not greatly inclined to the galactic equator. The observations

are consistent with the assumption that the principal force governing the motions is gravitational with the center of mass near the galactic center. The period of rotation at the sun's distance from the center is $2 \cdot 10^8$ years.

There are, at the present time, two programs in progress which will attempt to establish absolute stellar proper motions using the distant galaxies as a reference frame, the assumption being made that those objects do not show any systematic rotation with respect to the local inertial frame of rest.

A large number of proper motion studies of galactic clusters has been carried out in order to establish membership of the individual stars in the field. Because of the high internal precision required for this work, these studies have been confined primarily to long-focus telescopes, with plates taken over time intervals of 50 or more years.

Several surveys of the sky for stars with high proper motion, largely with the aim of finding absolutely faint stars, have been carried out over the past several decades. Two surveys are still in progress, one with the 48-inch Schmidt telescope at Mt. Palomar and the other with the 13-inch telescope at Lowell Observatory, the latter being by far the most extensive survey to date. It will cover 80 per cent of the sky to a limiting magnitude of 17, and in the course of its completion, upwards of 240 million star images will have been examined. In surveys of this magnitude, it is essential that telescopes of not too large focal length be used to limit the number of plates needed to cover the sky and that the "moving" stars be found by rapid scanning of the plates. These surveys have drastically increased the known number of white-dwarf, sub-dwarf, and faint red-dwarf stars, which, at the present time attract much interest among astronomers.

An important area within astrometry is the determination of the distances of individual stars. Because of the extremely small quantities to be measured, the ultimate in precision is required. The geometric method of measuring distances is based upon the surveyor's principle, the object is observed from both ends of a base line. In determining the trigonometric parallax of a star, the semimajor axis of the earth's orbit is used as the base line. Reliable individual distances have been measured in this way for several thousands of stars within 30 parsecs of the solar system. Beyond this limit, the annual parallactic effect measured against a background of more distant stars becomes so small that it cannot be measured accurately. On the plates taken with telescopes having the largest scale, the parallactic shift of stars near the limit of 30 parsecs amounts to no more than 3μ . Shifts of this order require series of photographic plates taken over several years for their measurement. This necessitates the use of telescopes with high stability in their optical systems and the application of the most refined techniques of photography and measurement. It is only since the turn of the century that sufficiently precise instrumentation and

techniques for this task have been available. The importance of stellar distance determination is realized from the fact that the distance of a star must be known before its intrinsic luminosity and its rate of energy generation can be determined.

Studies of the stars in the solar neighborhood have revealed that the majority of them are components of double and multiple systems. Since the motions of the stars within a system are governed by their mutual gravitational attraction, it is possible to determine their masses by use of Kepler's third law (see KEPLER'S LAWS OF PLANETARY MOTION), whenever their orbital motions and the parallax of the system become known. This is the only direct way masses of the stars can be determined.

Routine observations of the motions in binary systems began about 135 years ago. Originally all observations were carried out visually. Although this method continues to be used for close pairs, it has been largely replaced by a more accurate photographic method for wider pairs.

Various searches for double stars have produced some 65,000 visual binary systems, but for only a small fraction (approximately 50) of these systems are data available for determining the individual masses with an accuracy of 30 per cent or better. These masses range from about 0.08 solar mass for a star 3000 times less luminous than the sun to 6 times the sun's mass for a star 100 times more luminous than the sun. Larger masses, as high as 50 to 100 times the solar mass, are found among the very close binaries such as eclipsing and spectroscopic binaries. Although these objects cannot be resolved into individual components, their orbital motions can be determined from the periodic variation in light and radial velocity (observed Doppler shift).

Stellar masses smaller than the value of 0.08 quoted above have been discovered in recent years by intensive photographic studies of nearby single stars and components in double stars. These studies, representing the ultimate in accuracy in photographic astrometry, have revealed unseen companions of such small masses that, according to theoretical estimates, they are either stars so small that they will never burn nuclear fuel or planets of the size of Jupiter.

Aside from demands for such utilitarian purposes as navigation, geodesy and space research, astronomers themselves are making heavy demands for substantial gains in quality and quantity in astrometric observations, extended to fainter and fainter stars.

The discovery of the intrinsically faint stars in the solar neighborhood has demanded an extensive parallax program with an entirely new telescope of special design.

Positions and space velocities on a large scale of the individual stars and of stellar systems within our galaxy are essential to understand its dynamics and evolution as well as the physical properties and evolution of the individual stars which populate it.

To accomplish this, new instrumental and

analytical techniques are currently being introduced which take advantage of the latest technological developments in automation.

ASTRONAUTICS, PHYSICS OF

Future historians may record that the age of space flight marked a turning point in modern times. Its physical principles—the laws of motion of celestial bodies—marked the turning point of medieval times. From Copernicus to Kepler to Galileo to Newton, the Aristotelian myth of a man-oriented universe succumbed to the conception of a detached mechanically oriented universe, operating through laws which were a synthesis of the new knowledge gained in the formerly separate domains of terrestrial and celestial mechanics. Mankind never quite recovered from that detachment.

Weight and Weightlessness. In Newtonian mechanics, weight is understood to mean the force that an object exerts upon its support. This would depend on two factors: the strength of gravity at the object's location (things weigh less on the moon) and, as Newton called it, the quantity of matter in a body (its "mass"). At any given location, where gravity is fixed, mass can be measured relative to a standard by noting the extension of a spring to which it and the standard are successively attached. Alternatively, the unknown and standard may be hung at opposite ends of a rod and the balance point noted. However, by an entirely separate experiment, mass can also be measured by noting the resistance of the object to a fixed force applied horizontally on a frictionless table. The measured acceleration provides the required basis of comparison with the standard. Needless to say, all objects measure identical accelerations when freely falling in the vertical force of gravity. This merely means that, unlike the arbitrary force we apply horizontally in the experiment above, gravity has the property of adjusting itself in just the right amount, raising or lowering its applied force, to maintain the acceleration constant.

It was well known that objects appear to increase or decrease their weight (alter the extension of the spring) if the reference frame in which

the measurement takes place accelerates up or down. As gravity did not really change, however, most people were inclined to draw a distinction between *weight* defined as mg , where m is the mass and g is the local gravity field, and the *appearance of weight*, the force of an object on its support as measured by the spring's extension. One way to avoid the difficulty has been to speak of an *effective g*, which takes into consideration the frame's acceleration. For example, at the equator of the earth, we measure, say by timing the oscillation of a pendulum, the effective g , some 0.34 per cent less than the g produced by the mass of earth beneath our feet. If the earth were rotating with a period of an hour and a half instead of 24 hours, our centripetal acceleration at the equator would cause the effective g to vanish completely, our scales would not register, objects would be unsupported, and for all practical purposes we would be weightless.

Formally, we could state that any accelerating frame produces a local gravitational field g_{acc} that is equal and opposite to the acceleration. Thus, a rotating frame generates a centrifugal g_{acc} opposing the centripetal acceleration. We have at any point

$$g_{eff} = g + g_{acc} \quad (1)$$

where g is the field produced by matter alone (e.g., the earth). By identical reasoning, an object in orbit, whether falling freely in a curved or in a straight path, will carry a reference frame in which g_{eff} is zero, for its acceleration will always exactly equal the local g by the definition of the phrase, "freely falling."

This concept was placed on a firm footing by Einstein who maintained that Eq. (1) is reasonable not only in mechanics but in all areas of physics including electromagnetic phenomena. We arrive at the inevitable conclusion that we cannot distinguish by any physical experiment between an apparent g accountable to an accelerating frame and a "real" g derived from a local accumulation of mass. This central postulate of the General Theory of Relativity also unified the two separate conceptions of mass. An object resting on a platform that is accelerating toward it will resist the acceleration in an amount depending on its inertia. It presses against the platform with a force equal to that it would have if placed at rest on the surface of a planet with local field equal and opposite to the acceleration of the frame.

General Principles of Central Force Motion. The gravitational force between point masses is inverse square, written

$$mg = -\frac{\gamma m' m}{r^2} \hat{r} \quad (2)$$

where the center of coordinates from which the unit vector \hat{r} is described lies in m' , one of the masses. Thus, the force on m is directed $-\hat{r}$, toward m' and is proportional to $1/r^2$ with γ the constant of proportionality. The quantity g is the force on m divided by m , (or normalized force) for which the name "gravitational field of m' "

is reserved. Of course, if m were in the field of a collection of mass points, or even in a continuous distribution of mass, the summated or integrated g at the location of m would no longer be an inverse square function with respect to any coordinate center. However, in one special case, the inverse square functional form would be preserved: if the source mass were symmetrically distributed about the coordinate center. This would be the case if the source were a spherical shell or solid sphere, of density constant or a function only of r . The sun and earth can be regarded, at least to a first approximation, as sources of inverse square gravitational fields.

There are some important general statements we can make about the motion of an object placed with arbitrary position and velocity in a centrally directed force field, i.e., a field such as the one described, which depends only on distance from a central point (regardless of whether or not the dependence is inverse square). As the force has only a radial and no angular components, it cannot exert a torque about an axis through the center. This means that the initial angular momentum is conserved. Now angular momentum is a vector quantity and therefore is conserved both in direction and magnitude. It is defined $\vec{h} = \vec{r} \times \vec{p}$, where \vec{r} is the position vector to the mass of momentum \vec{p} . The direction of the angular momentum vector is thus perpendicular to the plane containing \vec{r} and \vec{p} . As this direction is permanent, so also must be the plane. The planar motion of the object can be expressed in polar coordinates, so that, by writing $\vec{r} = r\hat{r}$ and $\vec{p} = m(\dot{r}\hat{r} + r\dot{\phi}\hat{\phi})$, we find the specific angular momentum (angular momentum per unit mass) called h , to be

$$h = r^2\dot{\phi} \quad (3)$$

This too then must be a constant of the motion.

Consider now the rate at which area is swept out by the radius vector, dS/dt . We recall from analytic geometry that $dS = \frac{1}{2}r^2d\phi$. Thus

$$\frac{dS}{dt} = \frac{h}{2} \quad (4)$$

so that this is a constant of the motion as well. On integration, we conclude that the size of a sector that is swept out is proportional to the time required to sweep it out. In the case of a closed orbit, the total area S would then be related to the specific angular momentum as

$$S = \frac{hT}{2} \quad (5)$$

This sector area-time relationship is Kepler's second law of planetary motion which was induced from Tycho Brahe's observation of Mars without prior knowledge of gravity and its central character.

The Laws of Kepler. Kepler stated two other laws of planetary motion: The orbits of all the planets about the sun are ellipses (a radical departure from the circles of Copernicus), and

FIG. 1. Kepler's second law. The sector area S swept out is proportional to the time required for the planet to move from a to b . Thus, if $t_{cd} = t_{ab}$, then $S' = S$ (from Berman A. I., "The Physical Principles of Astronautics," New York, John Wiley & Sons, 1961).

the squares of their period are proportional to the cubes of their mean distance from the sun, this mean being the semimajor axis of their ellipses. The third law pertained to the one characteristic common to all the planets: the sun. Taken together, the three laws led Newton to the concept of gravitational force and its inverse-square form.

By applying Newton's law of motion $\mathbf{F} = m\mathbf{a}$, a relationship between \mathbf{a} , the second derivative of the position vector, expressed in polar form, and \mathbf{F}/m or g , as given by Eq. (2), leads to the familiar conic solution for the trajectory of an object in an inverse square field,

$$\frac{1}{r} = \frac{\gamma m'}{h^2} + A \cos(\phi - \phi_0) \quad (6)$$

where A and ϕ_0 are constants. A rotation of axis will eliminate ϕ_0 , thereby aligning the coordinate axis with the conic's major axis. Also, by expressing the general conic, an ellipse or hyperbola, in terms of the usual parameters of semimajor axis a and eccentricity ϵ , we can relate the geometric parameters to the gravitational-dynamical constants, viz:

$$h = [\gamma m' a (1 - \epsilon^2)]^{1/2} \quad (7)$$

and

$$\frac{1}{r} = \frac{\gamma m'}{h^2} (1 + \epsilon \cos \phi) \quad (8)$$

Note that by substituting Eq. (7) into Eq. (5) and expressing the area of an ellipse as $S = \pi a^2 (1 - \epsilon^2)^{1/2}$ we arrive at Kepler's third law,

$$T = \frac{2\pi}{(\gamma m')^{1/2}} a^{3/2} \quad (9)$$

The energy of the orbiting object can be calculated with ease by evaluating it at an extremal point, say the nearest point to the gravitational

source, called pericenter or perifocus. As the energy is constant, it is immaterial where the calculation is made. Here the velocity has only an angular component so that the kinetic energy for a unit orbiting mass is $\frac{1}{2}v^2 = \frac{1}{2}r^2\dot{\phi}^2$. The potential energy at pericenter is $-\frac{\gamma m'}{r_{pe}}$ where r_{pe} is the distance of the unit mass from m' , the focal point. Here $\phi = 0$ so that by Eq. (8),

$$\frac{1}{r_{pe}} = \frac{\gamma m'}{h^2} (1 + \epsilon) \quad (10)$$

On substituting Eq. (7), we find the total kinetic and potential energy to be

$$E = -\frac{\gamma m'}{2a} \quad (11)$$

Our conclusion: All objects in orbit with the same major axes have identical periods and identical energies per unit mass. Knowledge of E is invaluable in determining an object's speed when its distance from the source is known, and *vice versa*.

In the event that the orbiting object's mass is not negligibly small compared with that of the gravitational source, one must take note that the combined center of mass, from which the acceleration is described, no longer may be assumed to lie in the center of the gravitational source. This complicates our equations somewhat, for the accelerating force still is expressed relative to the center of the source (if spherical). The adjustment that results, when center of mass coordinates are transformed to relative coordinates in the expression for acceleration, requires our equations to take the form $\gamma(m' + m)$ wherever formerly $\gamma m'$ appeared.

Disturbances in the Central Field. The earth, of course, is spherical only to a first approximation. More accurately, it is an ellipsoid of revolution about a minor axis—an oblate spheroid.

FIG. 2. Orbits of differing eccentricities and major axes which pass through a common point. Higher speeds correspond to higher energies and longer major axes (from Berman, A. I., "The Physical Principles of Astronautics," New York, John Wiley & Sons, 1961).

FIG. 3. The orbit of an earth satellite. The earth's equatorial bulge causes retrograde motion of the points of intersection n and n' of the orbit and equatorial plane. This can alternatively be interpreted as a retrograde motion, about the north-south axis, of the plane containing the closed orbit. The plane moves in the direction shown by the arrow in (b), maintaining a constant angle with the axis (from Berman, A. I., "The Physical Principles of Astronautics," New York, John Wiley & Sons, 1961).

Still more accurately, it appears to be slightly pear-shaped and, in addition, its figure is distorted by continuous local variations. The spheroidal figure, nevertheless, accounts for nearly all the anomalous effects of satellite orbits. For one thing, the gravitational force on the satellite is no longer centrally directed; the excessive mass in the equatorial plane produces a force on the satellite directed out of its orbital plane. The resultant torque causes the direction of the angular momentum vector to change; i.e., the plane containing the satellite's ellipse turns. The plane turns continuously about the polar axis maintaining its angle with the axis and with the equatorial plane constant. The turning rate is greatest for low orbits and small angles of inclination with the equator. For polar satellites, the plane remains fixed. A separate effect of this equatorial bulge perturbative force is the slow turning of the ellipse's major axis *within* the orbital plane. This effect vanishes at an inclination of 63.4° ; the major axis turns backward at inclinations above this angle and forward below.

Rocket Propulsion. A rocket operates by the simple principle that if a small part of its total mass is ejected at high speed, the remaining mass will receive an impulse driving it in the opposite direction at a moderate speed. As δm_e , the propellant, leaves at speed v_e with respect to the rocket, the remaining rocket mass m receives a boost in speed δv such that

$$\delta m_e v_e = m \delta v \quad (12)$$

If additional equal propellant mass is ejected at the same speed, the boost in rocket speed is slightly greater than before as the rocket mass has been slightly depleted by the prior ejection. Indeed, if the residual rocket mass eventually were minuscule, its boost in speed could reach an enormous value. The integrated effect of these nonlinear boosts is found as

$$v_t - v_0 = v_e \log_e \frac{m_0}{m_t} \quad (13)$$

where v_0 and m_0 are the rocket speed and mass at some arbitrary initial time and v_t and m_t are the same quantities at some time t later.

From these simple considerations, it is apparent that the highest rocket velocities are attained if we could increase the propellant speed as well as the mass ratio m_0/m_t . The mass ratio can be maximized by obvious methods such as choosing a high-density propellant which cuts the tankage requirement or avoiding unnecessarily complicated apparatus for ejecting propellant at high speed. A nuclear rocket, for example, may perform well in its ability to eject propellant an order of magnitude higher in velocity than conventional chemical rockets; nevertheless, the penalty required in reactor weight and shielding severely limits its effectiveness.

Specific impulse is one performance characteristic which applies to the propellant's ability to be ejected at high speed regardless of the weight penalty required to do this. It is the impulse produced per mass of propellant ejected, or $m \delta v / \delta m_e$.

or, by Eq. (12), simply v_e . In engineering usage, it is impulse per *weight* of propellant ejected, or v_e/g_e where g_e is the acceleration of gravity at the earth's surface. Its units are seconds, and it can be interpreted as the thrust produced by a rocket per weight of propellant ejected per second. By itself, thrust is of little importance unless it is sustained for a significant time by a large backup of propellant tankage. It is here that the mass ratio term in Eq. (13) would play an important role in any evaluation of a rocket's true performance.

Transfer Orbits. If one wishes to leave one orbit and enter another by rocket, an optimum path is generally chosen to minimize the total propellant required. Nevertheless, this should not be done at the expense of unduly long flight times, complicated guidance equipment, or high acceleration stresses. These would require unprofitable weight expenditures which would offset the frugality in propellant tankage.

FIG. 4. Four launch trajectories into a satellite orbit about a planet. (a) If that planet has an atmosphere, the rocket may ascend in a "synergic" trajectory from the planetary surface to the final orbit, i.e., it cuts through the denser portions in an initially vertical path and gradually bends over into a horizontal path during burnout. (b) If there is no atmosphere it may ascend from the ground in a ballistic ellipse. This same ascent path may be chosen if the departure is from a parking orbit or "space platform" close to ground level. A far better choice would be (c) the Hohmann ellipse, with pericenter at the planet's surface and apocenter at the satellite orbit. Burnout time is assumed short in both this and the ballistic case. (d) A vehicle such as an ion rocket, which can sustain a microthrust for a very long time, cannot be launched from the ground but only from a parking orbit. It will spiral out to the desired altitude with few or many turns about the planet, depending on the magnitude of the thrust relative to that of the gravitational force (from Berman, A. I., "The Physical Principles of Astronautics," New York, John Wiley & Sons, 1961).

Let us examine a simple but recurring example of a transfer problem, that of leaving a space platform in one circular orbit and entering another larger one concentric with the first. If the transfer path were radial or near radial (a so-called ballistic orbit) then one would have to launch at a large angle to the direction of motion of the platform, accomplished only by a velocity component opposed to the platform's motion. On reaching the outer platform, a soft landing can be made only by a substantial rocket velocity boost tangent to the orbit. Clearly, the total propellant expenditure would be far greater than one alternative of launching the rocket in the direction of motion of the first platform with just sufficient speed to reach the outer circle, timed so that the outer platform will meet the spacecraft. The transfer orbit will be an ellipse cotangent with both circles. The outer platform will be moving much faster of course at the contact point as the major axis of its orbit is much greater [see Eq. (11)], but the difference in speed is not nearly as pronounced as for the ballistic transfer case. A differential speed increment at contact completes the maneuver.

The return trip, from an outer to inner circle, is made by following the second half of this cotangent ellipse, named the Hohmann transfer orbit after the German engineer who discovered its optimal property with regard to propellant expenditure. In the return case, the spacecraft is launched in opposition to the outer platform's motion. This removes kinetic energy and forces the spacecraft to fall in closer to the attractive center in order to make cotangent contact with the inner circle. The total propellant expenditure from the outer to the inner platform is the same as for the original journey.

An interesting question arises if one wishes to leave a platform for an outer orbit when it initially is in an elliptical orbit rather than a circle. Should we depart from apocenter where we are furthest from the gravitational source and closest to our destination? Or should we depart instead from some other point in the ellipse? Paradoxically, our best launch point is at pericenter, for here the largest possible amount of energy will be transferred to the spacecraft for a given expenditure of propellant. A given thrust applied for a given time interval will do more work on the spacecraft when it is moving fast, as at pericenter, for it covers a greater distance during the interval. This advantage offsets the undesirability of being at a lower potential energy point at pericenter.

Powered Trajectories. In the usual operation of a solid- or liquid-propelled rocket, the propellant is depleted in a time negligibly small compared with the total flight time. The trajectory analysis may generally be considered as that of a free orbit subject to burnout initial conditions as in the discussion above. If, however, the propellant ejection is sustained over long periods, as in an ion-propelled rocket, the trajectory analysis is necessarily complicated, for, in addition to the varying gravitational force, the vehicle, of slowly

diminishing mass, is subject to a thrust which may be changing both in direction and magnitude. Even one of the simplest thrust programs, a constant thrust in the direction of motion, requires an electronic computer analysis in order to obtain the position and velocity at future times (see ELECTRIC PROPULSION).

The continuous-thrust trajectory is a spiral with many advantages over the orbital ellipses. First, the lower sustained thrust precludes the high acceleration stresses associated with rapid-burning chemical rockets. Much of the structural weight usually needed to withstand these stresses can be replaced by propellant. Also, flights to the extremities of a gravitational region may take a shorter time in a spiral trajectory. In a long Hohmann ellipse, for example, most of the journey is made at very low speed. In a powered spiral, on the other hand, the spacecraft could be made to move fast, for the thrust, though small, is integrated over many months.

The spiral concept is ideal for rockets where very high ejection velocities are feasible by using electromagnetic or electrostatic particle accelerators, but only at the expense of a low propellant flow rate and relatively heavy power-generating equipment. However, the propellant reserve, and thrust, could then last the required long time. Such an ion rocket with its very low thrust-to-weight ratio could hardly be expected to take off from the ground, and could only take off from an orbital platform. In the vacuum of space, the ion beam meets its ideal environment.

ASTROPHYSICS (See also ASTROMETRY, COSMOLOGY, SOLAR PHYSICS)

Starting with the advent of photography and the study of stellar spectra in the second half of the nineteenth century, astrophysics now includes optical and radio observations of stars, clusters, interstellar material, galaxies and clusters of galaxies, and their interpretation. Radiation from these external sources provides information on

the direction of the source, its velocity, composition, temperature and other physical conditions, including magnetic fields, density, degree of ionization, and turbulence. The term "astrophysics" is generally understood to include all these aspects except the measurement of direction (positions of stars in the sky and changes due to parallax and proper motion), and the orbits of planets, asteroids and comets (celestial mechanics). Because of its proximity, the sun can be studied in more detail than other stars; its structure and its influence on the nearby planets and comets are the concern of solar physics and are closely related to geophysics and stellar astrophysics. Study of the motions of stars in pairs, groups, clusters, associations, and galaxies is the overlap of celestial mechanics with astrophysics, and the study of the distribution and patterns of motion of the distant galaxies is the overlap with "COSMOLOGY."

Early studies of stellar spectra revealed differences due primarily to surface temperature and described by the sequence of spectral types ranging from "O" (30 000°K or more) through "B," "A," "F," "G," and "K" to "M" (2000 to 3000°K). The type of a spectrum is set by relative intensities of lines and bands due to ions, atoms, and molecules. The earth's atmosphere limits the wavelength region observable from terrestrial observatories since ozone and other constituents are opaque at wavelengths $\lambda < 3000\text{\AA}$, and water vapor bands block much of the region $1.2\mu < \lambda$

8μ . The ionized layers block radio waves longer than 20 meters. Nevertheless, thousands of spectrum lines, mostly in absorption, have been identified in the range $3000 < \lambda < 12000\text{\AA}$, and the pattern of lines within one spectral type has been found to vary with a second parameter, the "luminosity class" designated by roman numerals "I" (highly luminous "super giants") through "II," "III," "IV" to "V" ("dwarfs" of relatively low luminosity).

The continuum between spectral lines has an intensity distribution with wavelength that roughly matches Planck's theoretical distribution for a blackbody, $B(\lambda) d\lambda = 2hc^2\lambda^{-5}(e^{hc/\lambda kT} - 1)^{-1}$ where T is the temperature that accounts approximately for the ionization and excitation of atoms producing the star's line spectrum, or the dissociation of molecules producing bands—that is, for the spectral type. In so far as the lines can be ignored, the color of a star is approximately that of a blackbody of temperature T and the total ("bolometric") luminosity is given by $L_b = 4\pi R^2 \sigma T^4$, where R is the radius of the star and σ is Stefan's constant. The "apparent brightness" of a star (observed optical flux) depends upon its distance, D , and its luminosity in the wavelength region observed—approximately $4000 < \lambda < 6500\text{\AA}$ for visual observations and $3700 < \lambda < 5000\text{\AA}$ for photographic observations through glass optics. Recently the introduction of photoelectric equipment has allowed more accurate measurements in smaller wavelength regions. Standard measures are designated U (ultraviolet), B (blue), V (visual), I (infrared), etc., and are

usually expressed in magnitudes, an inverse, logarithmic scale. By successive approximations in such measurements of many stars, it has been possible to correct for the effects of interstellar absorption and limited wavelength range, as well as for the inverse-square law ($1/D^2$), to obtain total luminosities and colors. The luminosities are often expressed in "suns", that is, multiples of the sun's luminosity (about 4×10^{33} ergs/sec). Analogous measurements at radio frequencies are expressed as the flux in watts/square meter/cycle/second. Spectrophotometric measurements from rockets and artificial satellites above the earth's atmosphere have been made in the far ultraviolet, and it is to be expected that the intensity distribution, $I(\lambda)$, will soon be observed for all wavelengths.

The *masses* of stars are determined from motions of double stars, ranging from widely separated visual binaries whose relative motions can be photographed, to close spectroscopic and eclipsing binaries with orbits calculated from variations in radial velocity or observed Doppler shift. Among some 50 pairs, masses of individual stars are found from 0.08 to 20 solar masses, and there is less definite evidence of others as low as 0.03 and as high as 50 or 100. (One solar mass is 2×10^{33} gm.) Over most of this range the luminosity L is proportional to M^3 .

Astrophysical theory has achieved considerable success in explaining the spectra of stars by theoretical models of the atmospheres, involving the surface temperature, surface gravity, abundances of chemical elements, turbulence, rotation, and magnetic fields. The strengths of absorption lines are found to fit a "curve of growth," the relation between measured line strengths and the strengths predicted by quantum theory for unit abundance of the one ion, atom, or molecule involved. The theory of stellar interiors further relates mass M , luminosity L , and radius R with chemical abundances, the opacity of the material, and the generation of energy by nuclear reactions. More spectacularly, it has explained stellar evolution in terms of changes due to nuclear reactions.

The theoretical models of *stellar interiors* are based on stability and two modes of transferring energy outward to the surface: radiative transfer and convective transfer. Radiative transfer, by repeated emission, absorption, and emission of light, implies a temperature gradient dependent on the opacity and on the flow of radiative energy, or L . After calculating the opacity of gaseous stellar material (about 60 per cent hydrogen, 35 per cent helium, and 5 per cent heavier elements, by weight) at various temperatures and densities, the astrophysicist can compute the temperature, density and pressure in shells at various depths inside a star, starting with a definite radius and surface temperature, and adding up the shell masses to get the total mass. At some level, the temperature and density are sufficiently high for nuclear reactions to take place, the simplest being conversion of hydrogen to helium generating 7×10^{18} ergs of energy per gram. The rate of energy generation over the

whole inner core must match L . Calculations for convective transfer follow a similar pattern but depend upon matching the adiabatic gas law for over-all stability. A combined model may have a convective core surrounded by a radiative shell and that surrounded by an outer convective shell.

The successful fitting of nuclear energy generation into such gas-sphere models of stars by 1940 led to the idea of *stellar evolution*, the conversion of hydrogen to helium in its core causing a star to age. Direct evidence of this aging was first obtained from clusters of stars. The stars in one cluster, relatively close together in space, are assumed to have been formed at the same time, and the pattern of stellar characteristics differs from one cluster to another in a systematic way. The pattern is easily recognized on a Hertzsprung-Russell ("H-R") diagram of $\log L$ vs spectral type (or color) on which the vast majority of stars appear near a diagonal line, the "main sequence."

Several other classes of stars can be distinguished by location on the H-R diagram ("red giants," "white dwarfs," etc.) and theories of stellar evolution account for a change in location along an "evolutionary track" for any one star. The rate of such change will vary in general; for instance, the large-mass, high- L blue stars are expected to exhaust their hydrogen in a few million years, whereas yellow and red dwarfs remain for billions of years on the main sequence. H-R diagrams for clusters confirm the aging (also the theoretical star models and the assumption of cluster origin) and provide evidence of the age of each cluster.

A large part of astrophysical research is devoted to filling in the details of stellar evolution and the variety of nuclear reactions involved. For example, after its hydrogen is exhausted, the core of a giant star contracts and heats up to a billion degrees; then helium combines to form carbon, providing a new intense source of energy, and gas is probably blown off the star. Later, a small white dwarf remains.

The *formation of a star* starts with gravitational contraction of a large cloud ("nebula") of interstellar gas and dust, including matter ejected from previous generations of giant stars. The recycling of material back and forth from nebulae to stars involves changes in composition—the abundances of helium and heavy elements increasing with time. Since 1954, astrophysicists have therefore been concerned with *nucleogenesis*, the creation of the chemical elements in stars (or in an early stage of the evolving universe). Differences in composition of stars in various locations are now interpreted as evidence of past star making.

The *formation of the solar system* (sun, planets, asteroids, meteors, and comets) is one case of star formation studied in great detail by astrophysicists, geologists and chemists. Radioactive dating of minerals in the earth and meteorites places this event about four billion years ago when a slowly rotating nebula contracted, forming earth and planets, but losing a good deal of its mass in the process. Fractionation of chemical elements and compounds during the condensation

is linked with astrophysical interpretation of chemical analyses of meteorites and terrestrial minerals.

Interstellar material in the form of bright nebulae has been known since telescopes were first used. During the first two decades of this century, evidence was collected showing less obvious clouds of dust and interstellar gas in the plane of the Milky Way, based on the obscuring and color effects of dust and the spectral absorption lines of gas (primarily sodium and ionized calcium). In 1945 the polarization of starlight caused by the interstellar dust was discovered, and in 1950 the radio telescope added the emission by interstellar atomic hydrogen at 21-cm wavelength. This interstellar medium is now known to extend in a thin, flat slab centered in the Milky Way. When highly luminous blue stars are in or near it, the gas is ionized by ultraviolet radiation, and the resulting electrons produce emission lines of hydrogen, oxygen, helium and other elements by recombination or by electron excitation. In addition to such "H II regions," the dimensions of which depend on the temperature and luminosity of the exciting star and the density of the medium, astrophysicists have studied more complex nebulae in which the material density varies from one place to another. The interstellar medium is often denser near young clusters or individual blue stars, as expected from the theory of star formation.

The whole *Milky Way system* of stars, nebulae and interstellar gas and dust is assumed to be in dynamic equilibrium; that is, the mass distribution can be calculated from individual motions under the gravitational attraction of the whole galaxy, another important part of modern astrophysics. Since 1920 the dimensions of the galaxy have been determined from distances of the large bright globular clusters and from the distances of nearer stars. The resulting model, a flat disk with a high-density nucleus (total mass about 10^{11} suns) also fits the average motions of stars within a few thousand light years' distance from the sun, and the radial motions of cold atomic hydrogen out to 50,000 light-years determined by Doppler shifts in the 21-cm radio emission line. The stellar motions are derived from statistics of Doppler shifts and changes in direction, allowing for random individual motions differing from the general circulation. Most of the stars in the Milky Way share in a circular velocity, v_r , around the center of the galaxy, and the mass distribution is inferred from the observed decrease of v_r with distance from the center. The globular clusters and many other stars appear to move in orbits at high inclination to the Milky Way plane, forming a "halo" around the center having little or no angular momentum. It thus appears that there are two populations in the galaxy: "Population I" stars, nebulae, gas and dust in the outer parts of a thin rotating disk, and "Population II" stars in the nonrotating halo, probably formed at an earlier time.

The many *other galaxies* well outside our own are found to include some (classed as "spirals")

very similar to our Milky Way galaxy in structure and internal motions. Others are strikingly different (classed as "ellipticals"), probably due to different conditions of formation. All the techniques of astrophysics are being applied to the study of these objects: measurement of their sizes, luminosities, colors and masses, their proportion of interstellar material, the formation and evolution of their stars, etc. These physical characteristics are fairly well correlated with morphological type (spiral or elliptical), but the masses are found to be larger than expected for the measured luminosities. Moreover, some show signs of violent explosions, possibly due to extremely high densities reached in a collapsing mass of millions of stars.

Galaxies are observed in increasing numbers at larger and larger distances, roughly in uniform distribution but with marked clustering. There is some evidence that compact clusters contain a preponderance of ellipticals and that the small groups and pairs of galaxies tend to contain galaxies of only one morphological type.

The spectra of distant galaxies show large red shifts which, if interpreted as Doppler shifts, indicate a recessional velocity proportional to distance. Here astrophysics leads into COSMOLOGY and to the mathematical models of the universe based on general RELATIVITY. Observations have yet to confirm one or another of several different cosmological models, including one based on an assumed "continuous creation" of matter.

ATOMIC AND MOLECULAR BEAMS

This field of research utilizes a collision-free stream of neutral atoms or molecules as they traverse a vacuum chamber. With 10^{-6} mm Hg pressure in a vacuum chamber, air molecules at

room temperature travel on the average about 300 meters between collisions and move with an average speed of about 500 m/sec. Between collisions these molecules are essentially "free" and unperturbed by molecules of the residual gas or by atoms in the walls of the apparatus. The mathematical description of such isolated systems is much less complicated than for denser gases, liquids, or solids containing interacting particles.

Since 1911, when Dunoyer proved that a stream of neutral atoms would remain collimated in a vacuum, atomic- and molecular-beam research has become one of the most versatile, precise, and sensitive techniques for studying the properties of isolated atomic systems and interactions between such systems. Numerous fundamental discoveries in beam research have contributed to the present understanding of physical laws. The earliest experiments (1920) sought the molecular velocity distribution, which is important in the kinetic theory of gases. Atomic diameters (cross sections), van der Waals' interaction potentials, and polymer vapor composition were obtained after later refinements of technique. The Stern-Gerlach experiment (1924) demonstrated the validity of space quantization of angular momentum and established the electron spin as 1:2. This historic work placed quantum mechanics on a firmer foundation and initiated beam investigations of atomic and nuclear electromagnetic properties. Although many low-precision results appeared in subsequent years, high-precision spectroscopy began in 1937 with the introduction of the magnetic-resonance method by Rabi. In this method, transitions between quantum states separated by an energy $h\nu$ are induced by a radio-frequency field of frequency ν (h is Planck's constant). From the Heisenberg uncertainty principle, the width of the rf resonance is small, owing to the long lifetimes of the beam quantum states and to the ability to irradiate the beam with radio frequency for as long as a few milliseconds along its path.

Precision atomic-beam measurements have contributed to many theoretical and practical developments. The deuteron quadrupole moment (1939) pointed to the necessity of a tensor interaction in nuclear forces. The anomalous electron moment (1949) and the Lamb shift (1950) in the atomic-hydrogen fine structure were resolved by quantum electrodynamics. Nuclear spins (I) as well as magnetic-dipole (μ) and electric-quadrupole (Q) moments have been important in providing test information for the shell model (1949) and collective model (1953) of the nucleus. Atomic hyperfine-structure constants (dipole, a ; quadrupole, b ; and octupole, c), which describe the interaction between the electrons and the nucleus, as well as the numerous constants required to describe a molecule and its internal interactions, have contributed to the theory of atomic and molecular structure. The cesium "clock" or frequency standard (1952) represents a widespread practical application of beam technology

by using the hyperfine-structure transition at 9192.631770 Mc/sec (Ephemeris time) to regulate a quartz-crystal oscillator. Other frequency standards such as the thallium clock, ammonia maser (1954), and hydrogen maser (1960) also employ beam techniques for quantum-state selection. Very recent, high-energy nuclear accelerators have been equipped with atomic-beam sources to produce polarized protons.

Among nonresonant experiments, beams impinging on solid surfaces produce information on the wave nature of particles, work functions, and accommodation coefficients. Charge-exchange cross sections and interaction potentials are obtained from experiments with crossed beams, one neutral and one charged. Chemical reaction kinetics in isolated systems are studied in crossed beams of two reactants.

Four individuals have received Nobel Prizes for beam research: Otto Stern (1943) "for his contribution to the development of the molecular-ray method and for his discovery of the magnetic moment of the proton"; I. I. Rabi (1944) "for his application of the resonance method to the measurement of the magnetic properties of atomic nuclei"; P. Kusch (1955) "for his precision determination of the magnetic moment of the electron"; and W. E. Lamb (1955) "for his discoveries concerning the fine structure of the hydrogen spectrum."

A discussion of the energy levels of a simple atom and of one particular apparatus will illustrate the magnetic-resonance technique. An isolated atom in an external field, H , has energy states which are calculable from the Hamiltonian \mathcal{H}/h (Mc/sec) = $a \mathbf{I} \cdot \mathbf{J} + b$ (quadrupole operator $-g_J(\mu_0/h)\mathbf{J} \cdot \mathbf{H} - g_I(\mu_0/h)\mathbf{I} \cdot \mathbf{H}$, where some symbols have been defined pre-

viously, $g_J = \mu_J/(J\mu_0)$, $g_I = \mu_I/(I\mu_0)$, and μ_0 is the magnitude of the Bohr magneton. The first two terms represent the dipole and quadrupole hyperfine-structure interactions between the electrons and nucleus; the last two terms express the interaction of the electron and nuclear magnetic moments with the external magnetic field. For the simple case of $I = 1/2$, $J = 1/2$, $b = 0$, as in the ground electronic state of atomic hydrogen, the energy levels that arise from different "relative orientations" of the nuclear (I) and electronic (J) spins are shown in Fig. 1 as a function of the magnetic-field parameter $X = [(g_J + g_I)\mu_0 H]/\Delta W$. Here ΔW is the hyperfine-structure separation at $H = 0$. The levels are labeled by either the low-field quantum numbers (F, m_F) or by the high-field numbers (m_J, m_I), where $F = |I \pm J|$, and the m 's are the projections of F, I , or J along the field direction.

Of the many magnetic or electric resonance apparatuses, one specialized type has proved valuable for measuring atomic properties of both stable and radioactive isotopes. In Fig. 2, the "oven" or source, O, may take one of many forms—a microwave discharge to dissociate gaseous diatomic molecules, a closed tantalum crucible (with an exit slit) heated by electron bombardment, or one of many other devices for evaporating atoms. The atoms pass between the poles of three separate electromagnets (denoted A, C, and B, successively, from oven to detector). The inhomogeneous A and B magnets have eccentric cylindrical pole tips which produce a field gradient, $\partial H/\partial Z$. In this field, an atom experiences a force $\mathbf{F} = \mu_{\text{eff}}(\partial H/\partial Z)$, where $\mu_{\text{eff}} (- = \partial W/\partial H)$ is the negative slope of an energy level in Fig. 1. Within the homogeneous C field, a superimposed rf field induces state changes. Thus an atom which remains in a

FIG. 1. Hyperfine-structure energies (ordinate) of an atom with $J = 1/2$ and $I = 1/2$ in an external magnetic field (abscissa).

FIG. 2. Schematic of an atomic-beam, magnetic resonance apparatus.

single state [(1, 0) for example] is deflected similarly by the strong A and B magnets and follows trajectory 1 in Fig. 2. The stopwire, S, shields the detector from fast atoms and atoms with small deflections. If, in the C-field region, a transition occurs that causes the high-field slope ($\sim \mu_{eff}$) to change sign [e.g., (1, 0) \rightarrow (1, -1)], the A and B deflections are opposite, and the atom follows trajectory 2 to the detector D. A resonance is observed as an increase in beam intensity at the detector. Values of the constants in the Hamiltonian are deduced from the observed resonant frequencies of the atoms in known magnetic fields. Some detection methods in frequent use are:

(a) Deposition on a surface with subsequent assay by radioactive counting, neutron activation, or optical means (earliest detector).

(b) Ionization of alkali atoms on a hot tungsten wire, and measurement of the resulting ion current.

(c) Electron-bombardment ionization with subsequent mass analysis to discriminate against background gas ions. The beam ions are frequently counted by using electron multiplier tubes.

(d) Other detectors employing the principles of radiometers, pressure manometers, thermopiles bolometers, and changes in space charge.

ATOMIC CLOCKS

Atomic clocks make use of a property that is generally found only in systems of atomic dimensions: such systems cannot contain arbitrary amounts of energy, but are restricted to an array of allowed energy values E_0, E_1, \dots, E_n . If an atomic system wants to change its energy between two allowed values, it must emit (or absorb) the energy difference, for instance by emission (or absorption) of a quantum of electromagnetic radiation. The frequency f_{ij} of this radiation is determined by the famous relation

$$|E_i - E_j| = \Delta E = hf_{ij}$$

(h is Planck's constant). The rate of an atomic clock is controlled by the frequency f_{ij} associated with the transition from the state of energy E_i to the state of energy E_j of a specified atomic system (such as a cesium atom or an ammonia molecule). A high-frequency electromagnetic signal is stabilized to the atomic frequency f_{ij} and a frequency converter relates the frequency f_{ij} to a set of lower frequencies which then may be used to run a conventional electric clock.

The atomic frequency f_{ij} is, according to present knowledge, free of inherent errors; it is in particular not subject to "aging" since any

transition which the system makes puts it in a state of completely different energy, where it cannot falsify the measurement. Herein lies the principal advantage over other methods of time measurement. Two atomic clocks have exactly the same calibration as long as they are calibrated against the same atomic transition. Atomic readings made in Boulder, Colorado and Neuchâtel, Switzerland between 1960 and 1963 differed on the average by less than 3 msec, whereas the deviation of the astronomically measured time TU_2 from atomic time is of the order of 50 msec¹. For this reason, the atomic second was adopted as the new time unit, by the Twelfth General Conference on Weights and Measures, in October, 1964, and temporarily defined as the time interval spanned by 9 192 631 770 cycles of the transition frequency between two hyperfine levels of the atom of cesium 133 undisturbed by external fields.

The accuracy with which f_{ij} can be measured depends mainly on the degree to which the atomic resonator can be isolated from outside influences such as chemical and electromagnetic forces, and the extent to which Doppler shift can be avoided. Atomic transitions are chosen which have a minimum dependence on electromagnetic fields, and such fields as the magnetic field of the earth are carefully shielded out. Residual fields are nevertheless at present a major source of error in the most accurate clock. In many of the currently available clocks, the atomic systems are moving through vacuum with velocities of the order of 10^4 cm/sec. This motion introduces longitudinal Doppler shifts of the order $\sim 10^{-8} f_{ij}$. The transversal velocity causes only second-order shifts of the order $10^{-12} f_{ij}$. The transitions have to be observed mostly in the transverse direction, and residual longitudinal components must occur with either sign with equal probability, so as to produce, instead of shift, only a broadening that is symmetrical about f_{ij} . Whenever the systems collide with each other or are in contact with surrounding material, such as a buffer gas, they are perturbed by chemical forces and f_{ij} undergoes further shifts. Another source of error is the fact that most systems are observed only during a finite time τ . This circumstance gives rise to observation-time broadening of the order $1/\tau$ (typically, 10^3 cps). The error introduced hereby is not given by the broadening δf , but only by $\delta f/r$, where r is the signal-to-noise ratio with which f_{ij} is observed. However, if the phase shift of the observing system varies appreciably over the line width δf , additional errors known as "pulling" are introduced.

Two main problems have to be solved in atomic clocks: the atomic system has to be suspended without perturbation from chemical forces, and the frequency f_{ij} has to be measured. The most radical solution of the first problem is found in molecular-beam devices. The atomic systems are observed in free flight, and only during the relatively short transit time, so that observation-time broadening and Doppler shifts are large. Such devices have nevertheless provided the clocks with the highest accuracy so far, of the

order of a few parts in 10^{11} . The problems associated with Doppler shift and observation-time broadening can be alleviated by enclosing the atomic system in a box that is small compared to the wavelength $\lambda = c/f_{ij}$. The problem is to find atomic systems and wall materials such that the radiative process is not interrupted, and the frequency f_{ij} not appreciably influenced, during collision of the atomic systems with the walls. Instead of walls, a buffer gas can also serve as a "container" for the atomic systems. Very long observation times, giving rise to resonances of very high Q , have been produced by this technique. The accuracy of such clocks depends on the degree to which the influence of chemical forces can be neutralized. An indication of the accuracy of which such devices may ultimately be capable can be found in the fact that the measurement of resonance radiation due to Fe^{57} nuclei built into a crystal lattice has made possible frequency determinations with a relative accuracy of some parts in 10^{14} , and effects on time due to general relativity have been measured by this method. However, very high frequencies ($\sim 10^{20}$ cps) were involved, and no clock has been built for lack of a suitable frequency converter.²

The main methods of measuring f_{ij} are the following: in thermal equilibrium, the atomic systems in the lower-energy state outnumber the ones in the higher-energy state, and radiation of frequency f_{ij} induces more absorption than emission, giving rise to a net absorption signal. Several methods are known by which the population of either energy state is enhanced, giving rise to stronger absorption or emission signals. Particularly elegant is the maser principle. The higher-energy state population is sufficiently enhanced so that the emitted radiation itself can sustain the emission process. Often it is preferable to observe the absorption or emission of radiation of frequency f_{ij} indirectly. It is possible to observe microwave absorption via the change in the interaction of the absorbing atomic systems with optical radiation. Another example of indirect absorption is given by the atomic-beam method, where the microwave absorption is monitored by the deflection of the atoms from their trajectory. Indirect observation can be more economical since each microwave transition can be counted, whereas it takes several transitions to make a count by direct observation as long as the quanta to be counted carry less energy than the quanta of thermal radiation.

Several articles describing modern atomic clocks can be found in the Proceedings of the Third International Congress on Quantum Electronics, particularly in the third chapter of the first volume³.

ATOMIC ENERGY

The terms "atomic energy" and "nuclear energy" are used interchangeably in the contemporary literature to mean energy that originates within the atomic nucleus. Events that release atomic energy involve basic changes in nuclear structure and result in the formation of one or more different nuclides, which may be isotopes of the original atom or altogether different elements. The release of atomic energy is thus a more fundamental process than the release of chemical energy, which merely involves a regrouping of intact atoms into different molecular forms.

To date, three basic atomic energy mechanisms have been exploited in practical applications: (1) the fission of certain heavy nuclides; (2) the fusion of certain light nuclides; and (3) the process of radioactive decay. These will be discussed in the order listed.

Fission. In fission, a heavy nuclide splits into two lighter and predominantly unstable nuclides, commonly referred to as fission products, with the accompanying emission of several neutrons and the release of approximately 200 MeV of energy. Nuclides that readily undergo fission on interaction with low-energy or "slow" neutrons (< 0.5 eV) are referred to as fissile materials. There are three primary fissile materials:

(1) Uranium 235 which is a natural constituent of the uranium element and accounts for 0.71 per cent by weight of that element as found in nature.

(2) Plutonium 239, formed by neutron irradiation of uranium 238.

(3) Uranium 233, formed by neutron irradiation of thorium 232.

Uranium 238, which does not undergo fission on interaction with slow neutrons, does so on interaction with high-energy or "fast" neutrons (> 0.1 MeV). Table I lists representative fission energy distributions for the four nuclides cited.

A useful rule of thumb is that an energy release of 200 MeV per fissioning atom corresponds to an output of approximately one megawatt-day of thermal energy per gram of fissioned matter.

Practical applications of fission are based on the principle of a self-sustaining fission chain reaction, i.e., a reaction in which a neutron emitted by atom A triggers the fission of atom B, and one from atom B triggers the fission of atom C, and so on. For this to be achieved requires the assembly of a "critical mass" of fissile material, i.e., an amount sufficient to reduce the probability of neutron losses to a threshold value. The amount required depends on a number of factors, notably the concentration of the fissile material used and the composition and geometry of the reaction system.

There are two basic application concepts. One is the essentially instantaneous fission of a mass of highly concentrated fissile material in such a way as to generate an explosion force. This, of course, is what occurs in atomic weapons. Atomic explosives are also of interest in connection with peaceful uses such as large-scale excavation projects, a field of application that is currently being studied by the U.S. Atomic Energy Commission.

The other application concept is that of the controlled and gradual fission of an atomic fuel in a nuclear reactor, which may be designed for one or more of the following principal purposes:

(1) To provide fluxes or beams of neutrons for experimental purposes. This category of use includes research and materials testing reactors.

(2) To produce materials by neutron irradiation. Examples are reactors used primarily to produce plutonium for atomic weapon stockpiles or for the production of various radioisotopes for use in science and industry.

TABLE I. ENERGY DISTRIBUTION IN FISSION

Type of Energy	Quantity of Energy (MeV)			
	Slow Fission		Fast Fission	
	U ²³⁵	Pu ²³⁹	U ²³³	U ²³⁸
Kinetic energy of fission products	165	172	163	163
Kinetic energy of neutrons emitted	5	6	5	5
Instantaneous emission of gamma rays	8	7	7	7
Beta emission during fission product decay	9	9	9	9
Gamma emission during fission product decay	7	7	7	7
Total*	194	201	191	191

* Exclusive of nonrecoverable energy associated with neutrino emission during fission product decay. All numbers are rounded to the nearest integer. It should be mentioned that 8 or 9 MeV of additional energy become available in a nuclear reactor as the result of neutron capture and subsequent gamma-decay phenomena.

(3) To supply energy in the form of heat for such applications as the generation of electric power, the propulsion of ships or space vehicles, or the production of process steam.

The first demonstration of a fission chain reaction was achieved by E. Fermi and co-workers on December 2, 1942 when the world's first nuclear reactor (Chicago Pile No. 1) was successfully operated in a converted squash court beneath Stagg Field at the University of Chicago.

The most important application of fission promises to be in the electric power field. The basis for this expectation is that, if exploited efficiently, known and inferred deposits of atomic fuels represent a potential energy reserve many times larger than that of the fossil fuels (coal, oil and natural gas) on which the world's electric energy economy largely depends at present.

At this writing (1965), some 5000 electrical megawatts of atomic power capacity are in operation, under construction, or planned for construction in the United States. The amount of atomic electric capacity is expected to multiply more than tenfold by 1980, which would mean that atomic power would then account for 15 or 20 per cent of total U.S. electric power production. The U.S. Atomic Energy Commission has forecast that the atomic contribution may well increase to 50 per cent by the end of this century.

Fusion. Fusion is a general term for reactions in which the nuclei of light elements combine to form heavier and more tightly bound nuclei with the simultaneous release of large amounts of energy. In order for this to occur the interacting nuclei must be brought sufficiently close together to permit short-range nuclear forces to become operative. This means that one or both nuclei must be accelerated ("heated") to velocities sufficient to overcome the strong electrostatic repulsion that exists between particles having the same electrical charge. The velocities required correspond to particle "temperatures" of the order of tens or hundreds of millions of degrees, which in turn correspond to particle energies of thousands or tens of thousands of electron volts. The term "thermonuclear" reactions is reserved for fusion reactions in which both nuclei are traveling at high velocity (as distinct from reactions between an accelerated projectile particle and a static target nucleus, as in particle accelerator experiments).

The only practical application of thermonuclear reactions developed to date is in thermonuclear weapons (so-called "hydrogen bombs") in which the energy released by a charge of fissile material serves to create the conditions required to bring about the reaction of "fusionable" materials. The first test of a thermonuclear weapon, which was the first demonstration of a man-made thermonuclear reaction, took place on October 31, 1952 at a U.S. testing site in the Marshall Islands. Peaceful uses of thermonuclear explosives are being studied and have the advantage, relative to straight fission-based explosives, that problems of radioactive contamination

are greatly reduced. This reflects the fact that the nuclides formed by fusion are stable and hence, apart from neutron activation effects, the formation of radioactive substances is limited to the fission component of the explosive.

Research has been in progress for more than a decade on techniques for controlling the fusion process as a means of supplying energy for electric power generation. The thermonuclear reactions of primary interest in this context are the deuterium-tritium reaction:

and the deuterium-deuterium reactions:

Deuterium is a stable isotope of hydrogen with a natural abundance of 0.0015 per cent. Tritium is an unstable hydrogen isotope with a radioactive half-life of 12.3 years and is produced from lithium 6 by the neutron-alpha reaction. The latter thus represents a relatively expensive "fuel" for thermonuclear reactions; however, the ignition temperature of the deuterium-tritium reaction is roughly an order of magnitude lower than that of the deuterium-deuterium reactions and the energy release is greater.

In a controlled fusion system as presently conceived, the fuel is in the form of an ionized gas, or "plasma," confined by magnetic pressure within a high-vacuum apparatus. In effect, the plasma is held in a "magnetic bottle," thereby preventing fuel particles from dissipating heat in collisions with the physical walls of the apparatus. The objective is to achieve a situation in which an adequately hot plasma of adequate density can be magnetically confined for a long enough interval of time for the desired reaction to take place. One approach is to constrict and confine a high-current discharge of fuel ions and hold the resulting dense plasma in confinement while its temperature is raised by adiabatic compression or other methods. Another approach is to accelerate fuel ions to high energies and then trap them in a magnetic field, maintaining confinement long enough for a dense plasma to accumulate.

In experiments in various experimental devices, the time-temperature-density multiple has steadily been increased; however, there is as yet no conclusive evidence that true thermonuclear conditions have yet been achieved in any laboratory. Beyond laboratory demonstration of controlled fusion per se lies the problem of demonstrating that devices can be designed to produce more power than they consume and beyond that lies the problem of demonstrating the economic feasibility of practical thermonuclear power plants. Thus, at present (1965), controlled fusion is still at the stage of basic research.

The chief incentive for thermonuclear power

development is the promise of a virtually inexhaustible energy source, assuming the ultimate use of deuterium as the primary fuel.

Radioactive Decay. As radioactive atoms undergo decay by alpha, beta or gamma emission, heat is generated by the interaction of the radiation with surrounding matter. Devices that utilize this heat to produce electricity are known as isotopic power generators. A family of such devices is being developed by the U.S. Atomic Energy Commission for specialized applications requiring from fractions of a watt to tens of watts of electricity. Thermoelectric or thermionic techniques are used to convert the heat to electricity. Costs are presently about \$10,000 per watt of electrical capacity. With further development and with volume production of isotopic "fuels," costs are expected to be reduced to the order of \$100 per watt. At present, isotopic power generators are being used on an experimental basis in a number of applications such as navigational satellites, automatic weather stations and coastal light buoys, all of which require a compact power source that can operate unattended for sustained periods (months or years). In the case of space applications, alpha-emitting radionuclides such as plutonium 238 or curium 244 are mainly used as the fuel. In terrestrial applications, the principal fuel used to date is strontium 90, a beta emitter.

ATOMIC PHYSICS

It is generally accepted by those who inquire into the properties of matter that these properties can be understood in terms of small constituents called atoms. The nature and structure of atoms has been a principal subject of study by physicists and chemists during the first half of the twentieth century. As a consequence of the success of such studies, research into the structure of matter has become divided into two moderately well-separated fields. One of these concerns the further details of the structure of the atomic nucleus which is described under the terms "nuclear physics," and "high-energy physics." The other is a study of the behavior of large groups of atoms, and is generally described under the heading "solid-state physics." This article is devoted to the structure of atoms themselves, a field which, in a sense, lies between the fields of nuclear physics and solid-state physics.

The idea of atoms is very old and was known to the Greeks during the classical period. It appeared from time to time in medieval works, although the concepts expressed now seem to us

very vague. They seemed to have been based on the idea that there could be a limit to the divisibility of matter and, consequently, the idea of a final indivisible particle out of which large pieces of matter could be built.

At the beginning of the nineteenth century, it became clear that chemical reactions could be most simply explained if each chemical element is thought of as composed of very small identical atoms characteristic of the element. There thus arose a rather well-defined idea of a chemical element composed of identical atoms, as distinguished from a compound composed of groups of different atoms combined into molecules. During the latter part of the nineteenth century, the kinetic theory of gases made use of the idea of atoms, and molecules, in explaining the behavior of gases. By the end of the century only a few physicists and chemists still doubted the actual material existence and "reality" of atoms.

It is perhaps rather curious that the idea of atoms became really well established only after it became clear that the atoms were not in any true sense indivisible, but that instead they had a complex structure which could be extensively investigated. Since this investigation required equipment and methods which had been developed by physicists rather than chemists, physicists took the lead and the work has taken the name of atomic physics or the physics of atomic structure. It was inaugurated in the 1890's when J. J. Thomson first isolated and established the existence of electrons. He showed these to have only about 1/2000 the mass of the lightest known atom, hydrogen. He showed also that these electrons, as indicated by their name, carried negative electrical charges. It was later proved by R. A. Millikan that all the electronic charges are the same. Thus the identification of electrons, as small electrically charged pieces of matter, and as constituents of all matter, became firmly established.

Since it was clear that normal matter is electrically neutral, it had to be assumed that each atom contained a positive electrical charge, as well as negative electrons. J. J. Thomson developed the picture of a somewhat spherical jelly-like mass of positive electricity, in which electrons were located at various positions, and bound to them by quasi-elastic forces.

A principal means of investigating the structure of atoms has been the examination of the light emitted by the material in the gaseous state. This LIGHT is found to consist of a number of discrete wavelengths, or colors. Each of these wavelengths was associated, in the early days of this century, with a mode of vibration of the electrons in the positive jelly. In particular, H. A. Lorentz of the University of Leiden was able to show that such electrons, when placed in a magnetic field, would have their modes of vibration changed in a way that explained findings of P. Zeeman, who had made early observations of the wavelengths of the light emitted by a radiating gas in a magnetic field.

Nevertheless, the picture was unsatisfactory.

The number of different frequencies emitted by each atom was very much larger than the number of electrons which could be attributed to the atom. Furthermore, these frequencies did not show the harmonic relationship to be expected on the simple picture.

During 1910 and 1911, Sir Ernest Rutherford suggested an experiment, carried out by Geiger and Marsden, in which alpha particles from a radioactive source were scattered from thin foils. The angles at which the alpha particles were scattered were found to be such as could be best described by the close approach of a heavy positively charged particle, the alpha particle, to another heavier and more highly positively charged particle, representing the scattering atom. From the results of these experiments, Rutherford concluded that the mass in the positive charge of an atom, instead of being distributed throughout the volume of a sphere of the order of 10^{-8} cm in radius, was concentrated in a very small volume of the order of 10^{-12} cm in radius. He thus developed the idea of a nuclear atom. The atom was pictured as a small solar system with the very heavy and highly charged nucleus occupying the position of a sun, and with electrons moving around it, as planets in their respective orbits.

Although this picture of nuclear atoms served to describe the alpha-particle scattering experiments, it still left many questions unsolved. One of these questions referred to the apparent stability of the atoms. An ELECTRON moving around the nucleus would tend to emit radiation, to lose its energy, and thereby to spiral into the nucleus. Why did it not do so? Why did the atoms all seem to be quite stable, and all to be of approximately the same size, even though some contain 90 or more electrons, while hydrogen contains only one?

The first approach to a treatment of these problems was made by Niels Bohr in 1913 when he formulated and applied rules for "quantization" of electron motion around the nucleus. He postulated states of motion of the electron, satisfying these quantum rules, as peculiarly stable. In fact, one of them would be really permanently stable and would represent the ground state of the atom. The others would be only approximately stable. Occasionally an atom would leave one such state for another and, in the process, would radiate light of a frequency proportional to the difference in energy between the two states. By this means he was able to account for the spectrum of atomic hydrogen in a spectacular way. Bohr's paper in 1913 may well be said to have set the course of atomic physics on its latest path.

Out of the experimental work on the scattering of alpha particles and the theoretical work of Niels Bohr, there grew a fairly definite picture of an atom which could be correlated with its chemical properties. The chemical properties were determined in the first place by the nuclear charge. The nucleus contained most of the atomic mass and carried an electric charge equal to an

integral number of positive charges, each of the same magnitude as an electronic charge. This positive nucleus then accumulated around itself a number of electrons just sufficient to neutralize its positive charge and form a neutral atom.

The number of positive charges, or the number of negative electrons around the nucleus, was designated as the atomic number of the atom. These showed a close parallelism with atomic weights, and an even closer parallelism with the arrangement of atoms in the periodic system. Through the formulation of a number of rules based on Bohr's picture of quantized orbits, the periodic system of the elements could be understood. Hydrogen was given one electron, and helium two. The two electrons in helium constituted a "closed shell" which exhibited almost perfect spherical symmetry and chemical inactivity. Since the first two electrons constituted a closed shell the third electron in the case of lithium gave the atom properties very similar to those of hydrogen. Outside of the first closed shell could be placed eight more electrons to form a second closed shell in neon. The four outer electrons necessary for the atom of carbon provided a description of the chemical properties of that ubiquitous element, and the one electron short of a closed shell in the case of fluorine gave some understanding of fluorine's vigorous chemical activity.

Thus, during the years after 1913, the feeling grew that the chemical properties of atoms could be pretty well understood. The idea that there were undiscovered elements, as indicated by gaps in the periodic system, was reinforced. Systematic search has now discovered them.

However, it was not until 1925 that Bohr's ideas were developed into a mathematical form, complete enough and precise enough to permit their general application, under the name of quantum mechanics. This development, associated with the names of Dirac, Heisenberg, Schrödinger, provided the basic laws which permit, in principle, the complete and quantitative description of an atom consisting of a heavy positively charged nucleus, and surrounded by enough electrons to make the whole system electrically neutral.

The principal feature of quantum mechanics is that it ascribes to electrons something of the nature of waves. It requires that calculations of the motion of an electron in the neighborhood of a nucleus be made in terms of wave motion rather than the motion of particles. One has immediately the explanation of the stability of atoms. The waves representing the electrons cannot collapse to points, or to the small size of the nucleus, without involving extremely large amounts of "kinetic" energy. The ground state of an atom is determined as the balance between the attraction of the nucleus for the electron wave and what might be called the elastic resistance to compression of the wave itself.

Other states of the atom may be pictured as states of vibration of the electronic wave around the nucleus. The state with a minimum number

of nodes is the ground state, and states with more complicated vibration forms represent higher energies and are called excited states. The excited states are in general unstable in the presence of an electromagnetic field. Most excited states decay into states of lower energy with a lifetime of about 10^{-8} second. In the process, the atom radiates an electromagnetic wave of a rather sharply defined frequency, equal to the energy difference between the two states divided by Planck's constant h .

The details of these states and of their rates of decay can all be calculated in principle, although the calculation involves as much mathematical difficulty as any calculation of the behavior of a large number of particles interacting with each other.

One of the properties of electrons that became evident during the study of the optical spectra of atoms was that of ELECTRON SPIN. The suggestion was made by Uhlenbeck and Goudsmit in 1925 that one of the features of such spectra could be understood if each electron had associated with it a quantity called spin, which is similar in many ways to angular momentum. Each electron also has a certain magnetic moment which affects the energy in the presence of a magnetic field. This property also has been incorporated into the wave ideas of quantum mechanics, and may be thought of as leading to two similar waves existing at the same time but each corresponding to a different "spin."

It is widely believed that the subject of atomic physics is closed in principle except for detailed and complicated calculations which can be made with computing machines. On the one hand, physicists have gone on to investigating the detailed properties of the atomic nucleus. Most of these properties have little effect on the atoms themselves. On the other hand, the properties of atoms in combination, and the way in which they form large pieces of solid matter, has led to an extensive and comprehensive field known as solid-state physics. These two directions lead to the exciting frontiers of physics in the second half of the twentieth century.

ATOMIC SPECTRA

Fundamental Facts. Light from electric discharges in gases shows *line spectra* due to free atoms excited by electron collisions. Noble gases

and metal vapors produce almost pure atomic spectra, while discharges in molecular gases show both molecular *band spectra* and atomic line spectra. Some spectral lines can also be observed in absorption when white light is made to pass through the gas into a spectroscope. Under high spectroscopic resolution, all lines are found to have nonzero width. This is due to random motion (DOPPLER EFFECT) and disturbing influences of neighboring atoms, molecules, ions or electrons (pressure broadening); but even after allowance for these effects, a spectral line has a definite, generally very small, width due to radiation damping (natural width). Precision measurement of wavelengths or resolution of very fine structures requires light sources giving narrow lines—discharges at low gas and current density and low temperature or even atomic beams at right angles to the line of sight. *Continuous* atomic spectra are generally weak under laboratory conditions; in emission, they are due to recombination of an electron with a positive ion; in absorption, to the reverse process of photoionization.

The term atomic spectra includes positive ions, with the following terminology: spectrum of Na, *arc spectrum*, NaI; of Na⁺, Na⁺⁺, ...; first, second, ... *spark spectrum*, or NaII, NaIII, ... Spectra of highly ionized or *stripped* atoms are important in astrophysics and occur in high-temperature plasmas. Systems with the same number of electrons, such as Na, Mg⁺, Al⁺⁺ show marked similarities and are called *iso-electronic* sequences.

In the ultraviolet, visible or infrared, the spectroscope, in the form of a grating or interferometer, measures primarily the wavelength (λ) of the spectral lines. It is generally expressed in angstrom units (\AA) defined as 10^{-8} cm or, by recent international convention, the fraction $1/6056.12525$ of the wavelength of a line of the isotope 86 of krypton, in air under standard conditions. The wave number ($\tilde{\nu}$ or σ), the reciprocal of the wavelength in vacuo, is measured in cm^{-1} or kayser (K), or in millikayser (mK). The frequency ν is derived by multiplying by c , the velocity of light in vacuo; in the range of microwaves and radio frequencies, ν is measured directly.

In contrast to frequencies, intensities of lines are strongly dependent on experimental conditions, and special experiments are required for deriving quantities expressing the strength of a line as a characteristic constant of the atom. This can be defined in various forms; the *f*-value is a number giving the ratio of the absorptive or dispersive power of the line to that of the classical, harmonic electron oscillator of the same frequency; the transition probability or Einstein *A*-value is the probability, per second, of an excited atom emitting a light quantum.

Hydrogen-like Spectra. The spectra of atoms containing one electron only (H, He⁺, Be⁺⁺, ...) are very simple if the fine structure is disregarded; they form the basis of the classification and theory of atomic spectra. Balmer's empirical

discovery of a numerical relationship between the wavelengths of the visible hydrogen lines led to a formula expressing the wave numbers of all hydrogen-like spectra by one constant R , the charge number Z ($=1$ for H; $=2$ for He^+ , ...) and two integral numbers n, n' ($=1, 2, 3, \dots$):

$$\tilde{\nu} = Z^2 R(1/n^2 - 1/n'^2) = T_n - T_{n'} \quad (1)$$

A series arising from a sequence of values n' is characterized by regularly decreasing spacings and intensities of the lines towards increasing wave numbers. Substitution of $n=1, 2$ and 3 in Eq. (1) with $Z=1$ gives the Lyman, Balmer and Paschen series, in the ultraviolet, visible and near infrared respectively. The wavelengths of the Balmer lines $\text{H}_\alpha, \text{H}_\beta$ and H_γ ($n'=3, 4, 5$) are 6562.8, 4861.3 and 4340.5 Å. The Lyman α line, the resonance line of hydrogen, has the wavelength 1215.7 Å.

The relation of Eq. (1) can be derived theoretically by applying nonrelativistic quantum theory to a model consisting of a point electron of mass m and charge $-e$ and a fixed point nucleus of charge Ze . In the *Bohr-Sommerfeld* theory, this is done by imposing quantum conditions on the classical orbit of the electron; in the more rigorous Schrödinger theory, by solving the wave equation with the assumption of constant energy E . Provided $E < 0$ (bound state), it assumes discrete values, those of the stationary states of motion or the *eigenvalues* of the wave equation. Emission and absorption arise from transitions between two energy levels $E_n, E_{n'}$, with the frequency of the light given by

$$\nu_{n,n'} = (E_{n'} - E_n)/h \quad (2)$$

where h is Planck's constant. Equation (1) is a special case of Eq. (2), with $E_n = -h^2 Z^2 R/n^2$. Allowance for the motion of the nucleus of finite mass M causes R to differ slightly for different M ; it is given by $R_\infty/(1 + m/M)$ where $R_\infty = 109737.3 \text{ cm}^{-1}$.

The solution of the SCHRODINGER EQUATION for a mass point in space leads to 3 quantum numbers. In polar coordinates, with a force derived from a central potential $V(r)$, the quantum numbers n_r, μ and m give the numbers of nodes of the wave function in the range of the coordinates r, ϑ and φ . If a new set of quantum numbers is defined by $l = |m| + \mu, n = n_r + l + 1$, these are found to determine the values of the following constants of the motion: the z -component of the angular momentum is $L_z = m\hbar$, where $\hbar = h/2\pi$, the square of the absolute value is $|L|^2 = l(l+1)\hbar^2$ and the energy E depends on n and l only. For the special case of the Coulomb field $V \sim 1/r$, E depends on n alone: $E_n = \text{constant}/n^2$. An energy level E_n has to be considered as consisting of a number g of states of different l and m . This situation is described as *degeneracy*, and g is the statistical weight of the level. The degeneracy in m is due to the central symmetry of the force field and occurs in all atoms in the absence of external fields. The degeneracy in l is peculiar to the Coulomb field in nonrelativistic treatment.

Alkali-like Spectra. The spectra of the alkali atoms and their isoelectronic ions ($\text{Li}, \text{Na}, \dots, \text{Be}^+, \text{Mg}^+, \dots$) show lines arranged in series similar to those of hydrogen. Their wave numbers can be represented by empirical relations which are generalizations of Eq. (1). Series of term values T_n can be defined in such a way that $T_n \rightarrow 0$ for $n \rightarrow \infty$, and the observed wave numbers are equal to term differences $T_n - T_{n'}$ (Ritz combination principle). In contrast to Eq. (1), however, there are several series of terms, so that apart from n , a second index number l has to be introduced. The term values $T_{n,l}$ can then be identified with quantized values of $-E/ch$ and the index numbers n and l with quantum numbers, as implied by the letters chosen, if we assume that in these atoms one electron moves in a central force field different from a Coulomb field. This *valency* or *optical* electron has to be imagined as more loosely bound than the others and moving in the field of electrostatic attraction by the core consisting of the nucleus of charge Ze and the remaining $Z-1$ electrons. At large distances from the core, the field is like that caused by a single charge e as in hydrogen. At smaller distances, the optical electron penetrates into the electron cloud of the core and experiences an increased attraction. This picture leads to a qualitative understanding of the term diagrams and spectra of alkali atoms as exemplified for Na in Fig. 1, where terms with $l=0, 1, 2, 3, 4, \dots$ are conventionally described as *S, P, D, F, G, \dots* terms. For any given n , an energy level is the further below that of hydrogen (the term value the larger) the smaller l

FIG. 1. Term diagram of Na. Approximate wavelengths in angstroms. The doublet splitting of the terms is not shown.

becomes, because a smaller angular momentum decreases the centrifugal force and brings the electron closer to the core. Emission or absorption of radiation according to Eq. (2) does not occur for all pairs of levels but is subject to the *selection rule* $\Delta l = \pm 1$. Transitions from P levels to the lowest S level form the *principal series*. Its lines can also be observed in absorption since the lower level is the ground level; the first member is the well-known yellow *resonance* line. Transitions from D or higher S levels to the lowest P level form the *diffuse* and *sharp* series, those from F levels to the lowest D level, the *Bergmann* or *fundamental* series.

A feature that cannot be explained by this model is the *doublet* structure, a doubling of all except the S levels. It is due to the fact that the electron possesses a *spin*, i.e., an intrinsic angular momentum S of fixed absolute value given by $|S|^2 = s(s+1)\hbar^2$, where $s = \frac{1}{2}$, and connected with a magnetic dipole moment μ . The interaction of μ with the magnetic field due to the orbital motion, the *spin-orbit coupling*, causes any one energy level of given n and l (except for $l = 0$) to split into two levels. They are characterized by a new quantum number j associated with the total angular momentum resulting from vector addition of L and S . It can have the two values $j = l \pm s = l \pm \frac{1}{2}$. Optical transitions are subject to the selection rule $\Delta j = \pm 1$ or 0. The width of the doublet splitting increases with core penetration and thus with decreasing l ; it is most prominent in P terms. It decreases rapidly with increasing n and increases from Li to Cs. In the term symbol, j is written as suffix and the doublet character is indicated by superscript 2. For example, two transitions forming the yellow resonance doublet of Na are written $3^2S_1 - 3^2P_1$ and $3^2S_1 - 3^2P_2$. The absolute value of n ($= 3$ in this case) can be deduced by comparison with hydrogen (Fig. 1).

Since for all term values $T_n > 0$ for $n \rightarrow \infty$, the extrapolation of a series $T_n = T_{n'}$ for $n' \rightarrow \infty$ gives the term value T_n . If this is the ground term, chT_n is the ionization energy of the atom. A convenient conversion formula is $8066 \text{ cm}^{-1} = 1 \text{ eV}$.

Under high resolution, hydrogen-like spectra are found to have a rather complex structure known as *fine structure* (the same name is often applied to the much wider doublet or multiplet structures); it can be explained by a relativistic velocity dependence of the electron mass removing the degeneracy of states of different l , and by magnetic spin-orbit coupling causing a doublet splitting. In fact, these two effects are related since the spin itself is relativistic in origin. The theory gives the result that a hydrogen level of given n depends on j only, so that, e.g., $n = 2$, $l = 0$, $j = \frac{1}{2}$ should coincide with $n = 2$, $l = 1$, $j = \frac{1}{2}$. In fact, such terms show a small difference known as *Lamb shift*. Its existence can be explained by quantum electrodynamics.

The treatment of the core in alkali atoms as providing a central force field is theoretically justified by the *Pauli principle*. In spite of the mutual

electrostatic interaction between electrons, it is permissible to ascribe quantum numbers n and l to them individually. This is implied in the nomenclature describing, for example, a configuration of two electrons with $n = 2$, $l = 1$ by the symbol $2p^2$. The Pauli principle allows not more than $2(2l+1)$ electrons to have the same quantum numbers n and l (*equivalent* electrons). When this number is reached, a *closed sub-shell* is said to be formed, characterized by spherical symmetry of charge distribution and vanishing total angular momentum. Thus the two $1s$ electrons in He, the further two $2s$ electrons in Be and the further six $2p$ electrons in Ne form closed subshells. In He and Ne, all electrons permissible for a given n (1 or 2, respectively) have been filled in and the configuration is described as a *closed shell*.

Other Simple Spectra. Helium, and also Li^+ , Be^{++} , \dots , have two electrons, and the atoms in the second column of the periodic table Be, Mg (also B^+ , Al^+ , \dots) have two electrons outside closed shells. The analysis of the spectra leads to two systems of terms, *singlets* and *triplets*, with only weak intercombinations; the S terms are single also in the triplet system. These facts can be formally described, in analogy to alkali spectra, by vector addition of the two spins to form the two possible resultant spin quantum numbers $S = 0$ and 1. The first alternative produces singlets ($j = l$), the second triplets ($j = l \pm 1$, $l, l+1$) unless $l = 0$. This implies a strong interaction forming the resultant S of the two spins and a weaker interaction forming j . The latter interaction is the same magnetic spin-orbit interaction that causes doublet splitting in alkali atoms, but the former is, in a less obvious way, due to the electrostatic repulsion between the two electrons. In all the terms concerned, the symbol for the configuration shows only one electron to be excited, e.g., $1s2p$ in He, but owing to the identity of the electrons, it is not possible to attribute the excited state $2p$ to one particular electron. The situation is analogous to that of two identical, coupled, linear oscillators showing two normal modes of vibration, each involving both oscillators in a *symmetrical* and *antisymmetrical* way. Application of Pauli's principle to the wave mechanical description of this two-electron system leads to two energy states, one with parallel and one with antiparallel spins, $S = 1$ and 0 respectively. Elements in the subgroup (Zn, Cd, Hg) show similar singlet and triplet spectra; in the heavier elements, however, the magnetic spin-orbit interaction is no longer weak compared with the electrostatic repulsion, and the division into singlet and triplet terms has a very restricted meaning.

In the elements of the third column, B, Al, Ga, In, Tl, the single electron outside a closed subshell produces doublet spectra, but in contrast to the alkali spectra, the ground term is a P term.

Complex Spectra. If more than one electron outside closed subshells have values of $l > 0$, the spectrum and the term structures are more

complex. Very often, especially in low-lying levels, a description in terms of the Russell Saunders coupling scheme (L, S coupling) is possible because the electrostatic interaction predominates over the magnetic spin-orbit interaction. As a result, we can define terms, each of which is characterized by a set of values L, S (or a multiplicity $2S + 1$), and each term is split into levels, each characterized by a value of j , the highest of which is equal to $L + S$. The classification and terminology are obvious generalizations of those for two-electron spectra. For configurations of 3, 4, 5 electrons the possible multiplicities are respectively: doublets and quartets; singlets, triplets and quintets; doublets, quartets and sextets, etc. The strongest lines arise from transitions between terms of the same multiplicity. Such line multiplets are often recognizable by their characteristic groupings of the lines and their intensity ratios. The level spacings are governed by the *interval rule*: they are in the ratio of the j values, e.g., the levels of $^4D_{7/2, 5/2, 3/2, 1/2}$ have spacings in the ratio 7:5:3.

Other, often much more complex forms of coupling occur, especially in the higher levels, and L and S then lose their meaning. One important property of any level which always remains well defined is the *parity*, and the Laporte rule states that even terms combine only with odd terms and vice versa. If the configuration is defined, a level is even or odd if Σl is even or odd. Levels can often be described as mixtures of several terms or configurations, but only of the same parity.

Hyperfine Structure (hfs) and Isotope Shift. These structures are usually of the order of fractions of 1 cm^{-1} and generally require interferometric methods for their study. Hyperfine structure is primarily due to the magnetic interaction of the nuclear magnetic moment μ_N with the field produced by spins and orbital motions of the electrons. A level of given j splits into hyperfine levels, each characterized by a quantum number F , where F can assume the values $j + I, j + I - 1, \dots, |j - I|$. The nuclear spin I is a characteristic property of each nucleus and has integral or half-integral values for even or odd values of the atomic number. The structure of hyperfine multiplets is similar to that of fine structure multiplets, with F, I, j taking the place of j, S, L . However, there is often also an electrostatic interaction between the electrons and the nucleus if the nuclear charge distribution has no spherical symmetry. Deviations from the interval rule in hyperfine multiplets have led to the discovery of such nuclear deformations described mainly by the *quadrupole moment* Q . Hyperfine structures in ground states can be measured very accurately by methods of atomic beam resonance. Hyperfine structure studies lead to values of I , approximate values of μ_N and Q , and accurate values for the ratio of the two latter for different isotopes.

For different isotopes of an element, the spectral lines—or the centers of gravity of their hyperfine multiplets—are often displaced against

each other. This *isotope shift* is due to two causes: in the light elements, it is due to the difference in nuclear mass, though this *mass effect* is not as easy to calculate as that causing the difference in the Rydberg constant in hydrogen-like spectra. In the heavier elements, differences in size and shape of isotopic nuclei can cause quite appreciable isotope shifts. Studies of this *volume* or *field effect* have contributed to our knowledge of nuclear volumes and the dependence of nuclear deformations on neutron numbers.

Magnetic and Electric Effects. The effects caused by magnetic fields play a great part in research on atomic spectra, particularly in magnetic resonance methods. An external magnetic field removes the degeneracy due to the spherical symmetry of atomic force fields and causes the energy to depend on the magnetic quantum number m . This leads to the formation of the *Lorentz triplet* or *normal Zeeman effect* in singlet spectra and to the more complex structures of *anomalous Zeeman effects* in multiplet lines. Zeeman effects in hyperfine structures are especially important for the determination of nuclear spins. The *Stark effect*, due to electric fields, is of somewhat less importance. It causes the energy to depend on $|m|$ only, thus not removing the degeneracy completely. While magnetic splittings are proportional to the field strength, Stark splittings are generally proportional to the square of the electric field.

AUGER EFFECT

Definition and History. The *Auger effect* is the filling of an electronic vacancy in the atom by one electron from a less tightly bound state, with the simultaneous emission not of a photon but of a second electron from another less tightly bound state.

Following experiments by Barkla (1909) and Sadler (1917) in which the number of characteristic K x-rays emitted by material absorbing higher-energy x-rays appeared to be substantially less than the number of x-rays absorbed in the K shell, Kossel (1923) suggested that the remaining vacancies might be filled by a radiationless transfer of the excess energy to an emitted electron. This interpretation was reiterated by Barkla and Dallas (1924), who observed an increase in the number of electrons emitted when x-rays were absorbed. Wilson (1923) had observed in a cloud chamber, simultaneous ejection of two electrons from the same atom. It remained for Auger (1925, 1926) to make systematic investigations of this phenomenon in argon. The effect has since been called the *Auger effect*, and the ejected electrons have been called *Auger electrons*.

Principal Features. Auger showed that

- (1) The photoelectron and its Auger electron arise at the same point.
- (2) The Auger-electron track length is independent of the wavelength of the primary x-rays, but the photo-electron track length increases with x-ray energy.
- (3) The direction of ejection of the Auger electron is independent of that of the photoelectron.
- (4) Not all photoelectron tracks show a coincident Auger track.

Filling of vacancies by the Auger effect can occur for any vacancy for which there are two electrons in the atom sufficiently less tightly bound than a net positive energy is available for the ejected Auger electron. Because photon emission is more easily detected and has played such an important role in the development of quantum theory, it is not generally realized that Auger emission is much more probable. Only for vacancies in the K shell in atoms with atomic number above 32 and in vacancies in the outer two electron states of an atom does photon emission dominate. The Auger effect also occurs after capture of a negative meson by an atom. As the meson changes energy levels in approaching the nucleus, the energy released may be either emitted as a photon or transferred directly to an electron which is emitted as a fairly high-energy Auger electron (keV for hydrogen, MeV for heavy elements). Finally we note that each Auger process increases the positive ionization of the atom by changing one initial vacancy into two final vacancies.

Energy Spectra of Auger Electrons. *Auger spectroscopy* is the measurement of the number, energy, and intensity of lines present. The spectrum of Auger electrons resulting from a given vacancy is more complex than the corresponding photon spectrum. The energy of the Auger electron resulting from the filling of a vacancy V of energy $E(V)$ by production of vacancies X_i and Y_j of energies $E(X_i)$ and $E(Y_j)$ is

$$E(V - X_i Y_j) = E(V) - E(X_i) - E(Y_j) - \Delta E_{X_i Y_j}$$

where $\Delta E_{X_i Y_j}$ can be interpreted as either the

increase in binding energy of the Y_i electron due to an X_i vacancy, or vice versa. Exact calculation of the number of possible Auger transitions, their energies, and their relative probabilities necessitates the use of a relativistic intermediate-coupling theory. In the above notation, X and Y refer to the total quantum number of a group of levels, and i and j to the individual substates within the group. For most Auger spectra a relativistic single-electron approximation (jj -coupling limit) gives the number of transitions and, with an empirical $\Delta E_{X_i Y_j}$, the energies of the lines to a high degree of accuracy, inasmuch as the lines not accounted for in this approximation are weak and have energies almost equal to the strong lines. The Auger electron described above would be called a $V - X_i Y_j$ electron. The spectrum from an initial vacancy of total quantum number n consists of three well-separated groups which can be characterized as $n - (n + 1)(n + 1)$, $n - (n + 1)(n + m)$, and $n - (n + m)(n + m)$, where $(n + m)$ represents all electrons with quantum numbers equal to or greater than $n + 2$. Thus for a K vacancy we have K-LL, K-LX, and K-XY groups, where X and Y stand for all electrons of total quantum number 3 or greater. For an L_3 vacancy we have L_3 -MM, L_3 -MX, L_3 -XY, and similarly for L_1 and L_2 . But for the L_3 shell the groups do not appear to be well separated, as they do for the K shell, because of the overlapping L_1 and L_2 spectra (for example L_1 -MM frequently overlaps L_3 -MX, and L_2 -MM usually falls partly between L_3 -MM and L_3 -MX). Each of these major groups contains many lines even in the jj -coupling limit. Thus the K-LL group contains six major lines K- $L_1 L_1$, K- $L_1 L_2$, K- $L_2 L_2$, K- $L_1 L_3$, K- $L_2 L_3$, K- $L_3 L_3$. Except for the K-LL group, knowledge of Auger spectra is very rudimentary for almost all elements.

Relative Probability of Auger and x-ray Emission. The evaluation of the relative probability of x-ray and Auger emission for different initial vacancies, and the determination of the relative intensities of various Auger lines constitute one of the most important aspects of Auger effect research.

The *fluorescence yield*, ω_i , for any initial vacancy i is defined as the fraction of vacancies filled by emission of *photons*. The *Auger yield* is defined correspondingly as the fraction filled by emission of *Auger electrons*. The Auger yield is divided into two parts, one (denoted by a_i) which transfers the vacancy to a level with a higher total quantum number, and the other (denoted by f_{ij}) which transfers the vacancy to a lower-energy vacancy with the same total quantum number. The latter process is called the *Coster-Kronig effect*.

For the K shell the following equation holds

$$1 = \omega_K + \alpha_K$$

Although in principle $\omega_K(Z)$ should be readily calculable, the number of (frequently relativistic) electron wave functions which must be known for each Z , and the number of permutations and

combinations of these functions which must be handled in order to calculate the individual probability of every line and, by summing, the total K Auger probability per unit time, present a formidable problem even with the aid of a sophisticated computer. The K fluorescence yield, ω_K , is therefore normally taken from experiment. Between $Z = 23$ and $Z = 90$, both ω_K and a_K are known to a few per cent or better. Below $Z = 23$, ω_K becomes so small that experiments sometimes disagree by a factor of 5. Above $Z = 90$, a_K is very small and is not known to better than a factor of 2. The following semi-empirical equation due to Burhop, with constants by Bergstrom, gives values correct to a few per cent between $Z = 23$ and $Z = 57$, and less accurate values outside these limits:

$$(\omega_K/1 - \omega_K)^{1/4} = 6.4 \times 10^{-2} + 3.40 \times 10^{-2} Z - 1.03 \times 10^{-6} Z^3.$$

Considerable experimental data exist in the literature for the relative intensities of the individual $V - X_i Y_j$ lines, especially for the K-LL group. Relativistic jj -coupling theoretical calculations for the latter group for atomic number 80 are in good agreement with experiment.

For the L shell in the jj -coupling limit the following equations hold:

$$\begin{aligned} 1 &= \omega_3 + a_3 \\ 1 &= \omega_2 + a_2 + f_{23} \\ 1 &= \omega_1 + a_1 + f_{12} + f_{13} \end{aligned}$$

In addition, the average L-fluorescence yield $\overline{\omega_L}$ for an atom with an L vacancy, having probability n_1 , n_2 , and n_3 of being in each of the three subshells, is

$$\overline{\omega_L} = 1 - \overline{a_L} = n_1(\omega_1 + f_{12}\omega_2 + f_{13}\omega_3 + f_{12}f_{23}\omega_3) + n_2(\omega_2 + f_{23}\omega_3) + n_3\omega_3$$

The values of the nine L-shell constants are much less well known than the two constants for the K shell. Below atomic number 50, the ω_i are all less than 10 per cent and appear to be less than 50 per cent for all elements. The f_{ij} go through sudden changes in value as certain transitions become energetically possible or impossible. For example, $L_1 - L_3M$ transitions are energetically forbidden for Z from 50 to 73.

The $\overline{\omega_L}$ and $\overline{a_L}$ clearly depend on the type of excitation. Although initial interest in the Auger effect arose through creation of vacancies by ejection of photoelectrons by x-rays, the strong recent upsurge of interest is the result of the studies of vacancies created in the decay of certain radioactive species. Internal conversion, shake-off accompanying beta-decay, and electron capture all create vacancies. In fact, the only method of studying the relative probability of orbital capture in the various shells and subshells of a nuclide involves the study of the x-ray or Auger spectrum of the product nuclide. The interpretation of these spectra necessitates the knowledge of the constants discussed above.

The importance of the Auger effect for radioactive nuclei, as well as the almost 100 per cent probability of Auger and Coster-Kronig emission for the M and higher levels, is indicated by measurement of the total charge accumulated by certain radioactive nuclei. For example, a vacancy produced in xenon $131m$ by internal conversion gives rise in some cases to as many as 21 Auger processes, leaving a xenon ion with a charge of $-22e$.

AURORA AND AIRGLOW

The visual aurora consists of luminous forms (arcs, rays, bands) in the night sky, usually confined to high latitudes, and based in the ionospheric E region (see IONOSPHERE). The airglow consists of a faint relatively uniform luminosity which is world wide in occurrence and, except under exceptional conditions, can only be observed instrumentally. The distinction between faint aurora and bright airglow in auroral regions is not clear.

The luminosity arises from emissions of the atmospheric constituents in the atomic, molecular or ionized forms. Table I shows the chief emissions in the visible region, with approximate intensities in Rayleighs for a bright aurora and temperate latitude airglow. There are many other emissions in the infrared and ultraviolet. In bright aurorae the colors can be seen visually; faint aurorae appear greyish white since the color vision threshold (except in the red) is above the visual threshold.

An auroral arc is a narrow horizontal band of light up to hundreds of kilometers long (usually geomagnetic east-west). The term arc derives from its appearance from the earth's surface due to perspective. A band is a portion of an arc showing distortion normal to its length. Auroral rays have been likened to searchlight beams; they lie along the geomagnetic field direction and may be several hundred kilometers long. Arcs and bands may be homogeneous or rayed.

Isolines of auroral occurrence are approximately centered on the geomagnetic poles. The auroral zones are defined as the regions of maximum occurrence. They are roughly circular with a radius of approximately 23° of latitude. The northern auroral zone reaches its lowest geographic latitude over eastern Canada; the southern, over the ocean south of Australia. At times of geomagnetic disturbance the aurora

TABLE 1. CHIEF AURORAL AND AIRGLOW EMISSIONS IN THE VISIBLE REGION*

Emission	Spectral Region or Wavelength	Approximate Height (km)	Approximate Intensity (Rayleighs)	
			Bright Aurora**	Nightglow
[OI]	5577Å	90-110	100,000	250
	6300,6364Å	160	50,000	150
NII	Blue to red		25,000	
H (Balmer Series)	Red, blue	E layer	1,000	
N ₂ (1st Positive)	Red	D layer	50,000	
(2nd Positive)	Violet	D layer	100,000	
N ₂ ⁺ (1st Negative)	Blue-violet		165,000	
O ₂ ⁺ (1st Negative)	Red-yellow	D layer	10,000	
NaI	5890,5896Å	80-90		100 (winter) 20 (summer)
OH	Red-yellow	60-100		100
O ₂ (Herzberg)	Blue-violet	90-100		15

** International Brightness Coefficient III (brightness of moonlit cumulus clouds).

NOTE. Emissions are highly variable or absent with type and latitude of aurora. Heights are given only when well-defined.

appears at lower latitudes and in very great magnetic storms may be observed in the tropics. The frequency of occurrence of aurorae at lower latitudes correlates with the cycle of solar activity.

Two pieces of very recent work have thrown doubt on the significance of the idea of the auroral zone. The first is the discovery of a relatively uniform auroral glow over the polar cap, extending through and beyond the classical auroral zone, on which auroral forms appear as brighter patches, which are visible merely because of contrast with their surroundings. The second is the suggestion of a local time dependence in the daily maximum of auroral occurrence which is at about 68° geomagnetic at midnight and 75 to 80° at noon. An inner auroral zone at 75 to 80° geomagnetic could possibly explain the observed results; the evidence is inconclusive.

Many auroral forms are probably caused by the precipitation of particles (mainly electrons) into the ionosphere. Their origin is obscure, but recent investigations suggest that they are derived from the outer regions of the magnetosphere, and are accelerated and precipitated in an irregular manner on the high latitude side of the outer radiation belt through some mechanism (e.g., turbulence) which is probably related to the solar wind. It is doubtful if precipitation of trapped particles from the outer radiation belt causes aurora directly, except in great magnetic storms (see RADIATION BELTS).

A strong ionospheric current system is seated approximately in the classical auroral zone, but the detailed relation between aurorae and the electric currents is obscure.

The so-called radio aurora signifies the ionization in the E layer that is associated with magnetic disturbances, and gives rise to characteristic type radio reflections in the VHF (30 to 300 Mc/sec) band and less often at higher frequencies.

It has often been suggested that radio aurora may be identified with the optical aurora, but little real evidence exists for this. It is thought that the correspondence between them may be only random.

The chief characteristic of the ionization is that it is aligned along the earth's magnetic field, the size of the irregularities ranging from meters to kilometers in length. The mechanism producing it is obscure; wind shears and particle precipitation probably contribute.

The pattern of ionization usually shows a systematic movement which in and below the auroral zone is statistically very similar to the ionospheric disturbance current system, but there are difficulties in interpreting the movement as that of the electrons in the current system. Other interpretations are that the movement is that of the ionizing source, or even sound waves.

Frequently electromagnetic noise emission (hiss), centered around 8 kc/sec, is observed in association with aurora. Recent satellite observations have sometimes shown detailed correspondence between electron precipitation, auroral light intensity, and hiss, but at other times the correlation is poor. Theories of this noise emission all consider the interaction of a stream of particles with the surrounding plasma. Travelling wave tube amplification, Cerenkov radiation, or Doppler-shifted cyclotron generation by protons have been suggested.

The airglow is subdivided into the dayglow, twilightglow and nightglow. The sodium intensity in the nightglow and twilightglow is highest in local winter, but seasonal and diurnal variations of the other emissions are not clear as there are marked latitude effects and distinct patchiness. The origin of the nightglow is obscure, though an important part of the oxygen red emission is excited by electron-ion recombination in the F

layer. At the 85 to 100 km level there are complex chemical reactions involving oxides of nitrogen as well as the free gases and ions. The energy sources are far from understood: winds, turbulence, the quiet day ionospheric current system, thermal excitation and even particles probably contribute.

Recent research has considerably extended our knowledge of aurora and airglow. In the next few years solution of many of the problems may be expected.

BALLISTICS

Ballistics is an applied science dealing with the position, velocity, and acceleration of bodies in space and the forces influencing them. It is considered a branch of applied physics or MECHANICS and was formerly concerned primarily with military projectiles such as rifle bullets, field artillery shells, bombs, and rockets, but now has a bearing upon missiles, space vehicles, and orbiting satellites. Interior ballistics is concerned with the motion generated within the gun barrel or container, exterior ballistics is concerned with the motion in free air, and terminal ballistics is concerned with the effects at the point of impact (hopefully, at the target). Some bodies in motion will not involve all three divisions of this subject, for some are not launched from a gun barrel and some have no definite target or impact point (such as a vehicle which ends up orbiting the sun).

In designing a gun and a bullet, an attempt is made to obtain the highest velocity with the lowest possible maximum gas pressure. The burning rate of the propellant is important and this can be controlled by the shape and size of the pieces of propellant used. The erosion of the inside of the barrel must be held at a minimum in order to retain accuracy and keep down the heating of the barrel. It is said that some of the large German guns in World War I could be fired only once a day because they got so hot it was necessary to allow them to cool off in between firings. The smoke and the flash should be held at a minimum. Early inventors struggled with the problem of measuring projectile velocity and gas pressure in the gun barrel. The first crude method of indicating gas pressure was merely to note whether or not the gun barrel burst. When it did burst, the gas pressure had been increased too much! Great progress was made when Benjamin Robins developed the ballistic pendulum, a description of which he presented before the Royal Society of England in 1742. This involved computing the velocity of a projectile by measuring the swing of a large pendulum catching the shot. It was possible to estimate the velocity at the target as well as near the muzzle. Other methods involved the Boulengé chronograph, which measured the time elapsed between the breaking of two wire screens in the path of the shot, and the use of a magnetized projectile fired through

two coils in series which recorded the induced voltage as a function of time. Improvements came through the use of strain gauges cemented to gun barrels and x-rays to locate the position of the projectile in the barrel as a function of time, and by comparing emissivities in two spectral regions to measure or estimate the temperature of the gas.

In exterior ballistics an effort is made to trace or plot the entire trajectory of the projectile. When the target is fixed, errors of firing can be observed and corrected quickly; but when bombing is done from a plane or when the interception of a missile is attempted by launching another missile, errors of sighting or launching cannot be corrected as quickly, for the plane cannot return to its former position exactly and a second missile to be intercepted is not apt to follow the same trajectory as the first one. The first attempts to predict trajectories of shells were made on an assumption that gravity was the only force acting upon the shell, but as muzzle velocity became greater, the air resistance became many times more important than gravity. The shape of the shell became more important, and as pointed noses were designed, it became necessary to devise some way to stabilize the projectile. The shells were spun by spiral grooves inside the barrel while bombs, rockets, and missiles were equipped with fins.

As missiles became larger and more powerful they left the atmosphere of the earth sufficiently to be affected by the motion of other planets. It was difficult to record their trajectories. One method used in 1956 was to mount powerful strobe lights on the missiles and program them to flash in certain patterns. A radio signal was sent to the earth simultaneously with the flashes of the lights. Large ballistic cameras were set some on islands, along the path of the missile; and their shutters were left open during the entire flight of the missiles. The camera plates recorded the flashes of the strobe lights and also the star trails. The flights were made at night and it was important to have a clear night with no clouds. The star trails aided in the exact orientation of the cameras. An electronic computer program was devised to synchronize the timing records of the ground receiving stations and the light flashes so that the position, velocity, and acceleration of the missile were quickly computed. Computer programs were even developed to the point when the computer would predict the point of impact

from the early observations before the missile landed, usually in the ocean.

Terminal ballistics, which is concerned with fragmentation, blast, and penetration of armour and concrete, cannot be covered in detail in this brief article.

BAND SPECTROSCOPY

Theory, Instrumentation, Interpretation, and Applications. The term "band spectrum" is used to designate a spectrum originating either by emission or absorption in the molecules of a compound. As such, it is to be distinguished from a line spectrum, which is the designation of a spectrum originating in the atoms of a chemical element. It should not be assumed that the appellation band spectrum is necessarily descriptive. It is to be considered mainly of historical significance originating at a time when low-dispersion instruments were generally used for observation, which imparted an appearance of unresolved bands to many of these spectra. Actually, if an exception is made of pure rotational spectra in the far infrared region, all band spectra are highly complex when observed under high resolution. The optical radiant energy identified with molecular spectra is distributed over a very wide range of frequencies extending from the ultraviolet to the far infrared, in effect joining the microwave region at wavelengths of the order of 1 mm. The dynamic conditions accounting for this distribution will be examined briefly.

The essential differences between atomic and molecular spectra are accounted for by the fact that the former are completely explained by quantized changes in the energy associated with the outer electronic structure, whereas the latter include not only this energy, but also contributions of energy resulting from the vibration of the component atoms relative to each other and from rotation of the molecule as a whole about an axis through the center of gravity. The actual energy pattern may be represented by a summation of these three contributions; that is, we may write $E = E_e + E_v + E_r$, or following the usual notation when the energy is expressed in wave number units or term values, $T = T_e + G + F$. All three forms of energy are quantized but it may be shown that in some cases vibrational frequencies are the same as those predicted by classical mechanics. It is not necessary that all three forms of energy be present. There are instances of pure rotational energy. Since this energy is relatively small, such band spectra are found only in the far infrared beyond 20μ .

Probably the outstanding example of a completely described rotational spectrum is to be found in the paper dealing with water vapor by Randall, Dennison, Ginsberg, and Weber.¹ Vibrational spectra with rotational structure are also of frequent occurrence. Owing to the magnitudes of interatomic forces, these are found in general between 3 and 15μ .

Beginning with the observation of rotational fine structure of H_2O vapor by Eva von Bahr in 1913, and the subsequent observation of the same spectrum and those of the halogen acids by Sleator and Imes^{2,3} a short time later, the quantum interpretation of band spectra developed rapidly. The body of information on this subject is remarkably complete. It may be stated safely that all observable features of well-resolved spectra of molecules in the vapor state may be completely accounted for both within the framework of classical quantum theory and that of wave mechanics.

The most complete discussion is to be found in two books by Herzberg.^{4,5} The notation introduced in the following sections follows for the most part that employed by Herzberg. A fairly detailed treatment has been given by Ruark and Urey.⁶ Attention is also called to review articles by R. S. Mulliken⁷ and by D. M. Dennison.⁸ As the development of the subject is lengthy and detailed, only a few basic concepts are included here. In general, the theory is built up by extensions of these ideas.

In the development of the quantum theoretical explanation of the detailed features of molecular spectra, it is customary to begin with the spectra of diatomic molecules. This introduces a relatively greater degree of simplicity because one is dealing essentially with a two-body problem. Furthermore, the full details of diatomic spectra are frequently completely observable, whereas the complexity of the spectra of polyatomic molecules is in general so formidable that the

details may be resolved in relatively few instances, usually where considerations of symmetry permit a simplification of the model. The general features of polyatomic molecules may be explained by extending the concepts developed for diatomic molecules.

A physical model may be conceived for the diatomic molecule which closely represents its actual features and properties. It is thought of as a dumbbell structure. First we think of it as a rigid rotator with an axis through the center of mass perpendicular to the line joining the nuclei of the constituent atoms. A wave-mechanical treatment of this rotator leads to the following expression for the quantized energy:

$$E_{\text{rot}} = J(J+1) \frac{h^2}{8\pi^2 I}$$

where h is Planck's constant, I is the moment of inertia and J is the rotational quantum number which can take a series of integral values 0, 1, 2, This formula is generally written $F(J) = BJ(J+1)$ where the constant

$$B = \frac{h}{8\pi^2 cI}$$

Each rotational energy state is characterized by one of these J values. The quantum mechanics also leads to a requirement for a selection rule for transitions between energy states $\Delta J = \pm 1$. Since such transitions account for the emission or absorption of spectral lines the frequency of such lines is given by

$$\nu = F(J+1) - F(J)$$

or

$$\nu = 2B(J+1); J = 0, 1, 2, \dots$$

This leads to a series of equidistant lines. Such spectra are actually observed in the far infrared. The actual frequency of rotation of the rigid rotator may also be derived and turns out to be

$$\nu_{\text{rot}} = c2B\sqrt{J(J+1)} \approx c2BJ$$

That is, for any state characterized by J , the rotational frequency is approximately equal to the frequency of the spectral line that has this state as its upper state. Actually, the molecule is not strictly rigid. A correction of the simple formula is necessary to account for modification of the observed spectral features resulting from centrifugal stretching. The effect is tied in with the vibrational frequency of the molecule and leads to a modified expression for the rotation energy $F(J) = BJ(J+1) - DJ^2(J+1)^2$, where $D = (4B^3/\omega^2)$, ω being the vibrational frequency. This extra term is always small.

The dumbbell model is next considered as a harmonic oscillator, characterized by a simple harmonic motion of the constituent atoms along the line joining them under Hooke's law forces. Since the observed spectral frequency is in some instances equal to the classical vibrational frequency of a molecule of the described configuration, it is of interest to recall the formula for

simple harmonic motion

$$\nu_{\text{osc}} = \frac{1}{2\pi} \sqrt{\frac{k}{m}}$$

where k is the force constant, or force required to produce unit displacement, and m is the mass of the point moving with simple harmonic motion. For the model under consideration consisting of mass points, m_1 and m_2 , m is replaced by the reduced mass μ , equal to $m_1 m_2 / m_1 + m_2$. On the classical theory, only one vibration frequency is possible. The solution of the Schrödinger wave equation for the harmonic oscillation leads to the following equation specifying the vibrational energy states:

$$E(v) = h\nu_{\text{osc}}(v + \frac{1}{2})$$

where v is the vibrational quantum number that takes integral values 0, 1, 2, Transforming to term values the equation becomes

$$G(v) = \frac{\nu_{\text{osc}}}{c} (v + \frac{1}{2})$$

or

$$G(v) = \omega(v + \frac{1}{2})$$

where ω is the vibrational frequency in cm^{-1} . We thus obtain a series of equally spaced energy levels. The quantized emitted or absorbed energy in cm^{-1} takes place, respectively, by a transition from a higher to a lower or a lower to a higher vibrational state. The wave number characterizing such a transition is given by

$$\nu = G(v') - G(v'')$$

where v' and v'' are the vibrational quantum numbers of the upper and lower states, respectively. The selection rule that governs such transitions and which also has been accounted for by quantum mechanics is

$$\Delta v = v' - v'' = \pm 1$$

It may be noted immediately that

$$\nu = G(v+1) - G = \omega$$

indicating that the quantum mechanically derived frequency is equal to the classical frequency for all transitions. Thus we are led to expect a single vibrational absorption or emission band. Actually weak harmonics of approximately integral multiples of the fundamental frequency are sometimes observed, corresponding to transitions with Δv greater than 1. The reason for the appearance of harmonics is that there is an anharmonicity introduced into the oscillating system owing to the fact that the interatomic forces depart somewhat from Hooke's law both on close approach and extreme separation approaching dissociation. This leads to a breakdown of the selection rule. The correction for anharmonicity is in general relatively small.

The complete expression for the vibrational energy expressed as a term value is a power

series including a quadratic and for extremely precise representation of wave numbers a cubic term in powers of $(v + \frac{1}{2})$. Thus we have

$$G(v) = \omega_e(v + \frac{1}{2}) - \omega_e x_e(v + \frac{1}{2})^2 + \omega_e y_e(v + \frac{1}{2})^3 \dots$$

where the subscript e refers to the equilibrium position. Neglecting the cubic term we obtain

$$\Delta g_{v+1/2} = \omega_e - 2\omega_e x_e - 2\omega_e x_e v$$

It is convenient to measure the levels from the zero point energy obtained setting $v = 0$. In this case, $\Delta g = \omega_0 - \omega x_0 - 2\omega_0 x_0 v$.

It is prerequisite to the emission or absorption of energy that the fundamental vibration cause a change in the electric dipole moment of the molecule; otherwise it is "infrared inactive." Illustrative of such inactive vibrations are those of diatomic molecules containing identical atoms such as O_2 or N_2 . In certain instances, inactive vibrations are observable as Raman effect displacements. Infrared and Raman effect observations therefore supplement each other advantageously.

The simultaneous occurrence of vibrational and rotational transitions accounts for the observed features of infrared spectra illustrated by those of the halogen acids.

The formulation may be summarized by combining the equations already given. The term value of the vibrating rotator becomes

$$T \quad G(v) + F_r(J) = \omega_e(v + \frac{1}{2}) - \omega_e x_e(v + \frac{1}{2})^2 + \dots + B_r J(J+1) - D_r J^2(J+1)^2 + \dots$$

From this we obtain the abbreviated form of the expression for the wave numbers neglecting the correction for centrifugal stretching:

$$\nu = \nu_0 + B_r' J'(J' + 1) - B_r'' J''(J'' + 1)$$

where the values of B are appropriate to the respective vibrational states and take into account the interaction between rotation and vibration. If we set $\Delta J = +1$ and $\Delta J = -1$, respectively, and replace J'' by J , the above equation reduces to the following two:

$$\nu_R = \nu_0 + 2B_r' + (3B_r' - B_r'')J + (B_r' - B_r'')J^2$$

$$J = 0, 1, \dots$$

$$\nu_P = \nu_0 - (B_r' + B_r'')J + (B_r' - B_r'')J^2$$

$$J = 1, 2, \dots$$

These formulas represent two series of lines which are called the P and R branches. If the vibrations were strictly harmonic and if there were no centrifugal stretching accompanying the rotation or interaction between vibrations, the branches of the band would consist of equally spaced lines extending each direction from the zero energy position of the vibration band. Actually taking these effects into account the P branch shows a gradual increase in the separation of components and the R branch a decrease.

Up to this point, only cases have been considered where the electronic state of the molecule remains constant during the occurrence of vibrational and/or rotational transitions. A large class of bands, mostly in the visible and ultraviolet regions, is accounted for by a change in electronic energy, similar to that responsible for line emission spectra, accompanied by vibrational and rotational transitions. The electronic energy represents the largest contribution and accounts for the spectral location. These bands are characterized by recurrent regularities known as progressions. A rotational fine structure is superposed on the regularities. A good example is the CN bands which occur in emission with great intensity in the carbon arc. The electronic levels are characterized by vibrational structures which in turn have rotational fine structure. There is no strict selection rule for the vibrational transitions, i.e., a transition can occur between any vibrational level of one electronic state and all the vibrational levels of the other. The set of bands arising from such a group of transitions forms a progression. Similarly each of these vibrational transitions is accompanied by rotational transitions yielding the usual P and R branches and in addition a Q branch resulting from $J'' - J' = 0$. This new selection rule is accounted for by theory, based on the fact that there is a difference in the angular momentum associated with the upper and lower electronic states.

The explanation of the features of the spectra of polyatomic molecules is developed naturally from the principles outlined for diatomic molecules. Instead of a single mode of vibration, a polyatomic molecule possesses several determined by point group theory. For a molecule of N atoms there are $3N - 6$ possible modes of vibration; $3N - 5$ for a linear molecule. A fundamental radiation frequency would be expected for each of these modes. Some however are inactive, as for instance the totally symmetric vibration of a linear symmetric molecule such as CO_2 . Except for what is described as a spherical top molecule, there are always several moments of inertia corresponding to various possible axes of rotation. In general there is always a possibility of angular momentum about an axis of symmetry. This results in an extension of the selection rule for rotational quantum numbers to $\Delta J = 0$ in addition to $\Delta J = \pm 1$. There is a Q branch in these instances. An exception is the linear molecule. For example a CO_2 band shows no Q branch. As in the case of diatomic molecules, a change in dipole moment is required for emission or absorption of energy.

Even moderately complex molecules show large numbers of vibration bands, either fundamentals or in general less intense overtone or combination bands. The rotational structure is resolved only in a few instances of relatively simple molecules where the available optical resolution can be brought to bear advantageously. Examples are CO_2 , CH_4 , and NH_3 . The observed absorption bands are generally envelopes that include the

rotational energy accompanying the vibrations. Most of them occur in the "rock-salt region" between 2 and 15μ . As may be expected, some modifications in the structure of a spectrum occur when the material is in the liquid or solid state.

Molecular Spectra. The spectrum of a molecule or an atom has been described as its most definitive characteristic. The fact that the spectrum is unique leads, of course, to applications in identification and analysis that are extremely useful and important. The term "fingerprinting" of molecules is of course familiar to all analysts. The spectrum not only establishes the identification of compounds but distinguishes between various types of stereoisomerism including *cis* and *trans* forms. In order to make the best use of spectra for identification, extensive libraries of spectral absorption curves have been assembled and are being extended. Among the first to attract widespread attention was the compilation by Barnes, Gore, Liddel, and Williams.⁹ An extensive set of spectra of hydrocarbons now numbered in the thousands represents a continuing effort by the American Petroleum Institute.¹⁰ A more recent program covering a wider range of chemical compounds is that sponsored by the Coblenz Society. The material collected by the organization is published and distributed by Sadler.¹¹

The utilization of infrared analytical methods has become an important tool for industrial research, particularly in support of those industries dealing with petroleum products, plastics, and organic chemicals. The manufacture of spectrophotometric equipment is of itself an important industry. The developments in this field have been covered by biennial survey articles in *Analytical Chemistry*. The survey articles in the infrared field, including extensive compilations of references, were initiated by Barnes and Gore¹² and continued by Gore.¹³ This series provides an essentially complete index to current literature.

It was suggested by Coblenz¹⁴, more than half a century ago, that the various radicals or structural elements of a molecule should contribute characteristic features to the absorption spectrum and that it might be possible to identify compounds on the basis of a synthesis of such features. The argument has considerable validity but is not entirely conclusive. Several correlations of atomic groups and absorption frequencies in the form of charts are available.

The first was that of Barnes, Gore, Stafford and Williams¹⁵, published in 1948. The well-known Colthup¹⁶ Chart was published in 1950. "Infrared Determination of Organic Structures," by Randall, Fowler, Fuson, and Dangel,¹⁷ is largely devoted to a correlation of spectral features with various types of bonding. It also contains a compilation of spectra in chart form. The use of spectral data has made possible the identification and determination of properties of many short-lived molecules or free radicals. Examples are Ca, CH, and NH.

Many physical and chemical properties of molecules can be inferred from spectral data. The

representation of a vibration frequency by a Hooke's law formula is recalled. Knowing the masses of the constituent atoms and the frequency, it is simple to derive the force constant associated with a given type of bonding and, from this, the heat of dissociation. Conversely, from a knowledge of bond strengths, the location of the fundamental frequencies may be predicted. The rotational structure permits calculation of the moments of inertia and derivation of interatomic distances. Interesting features of geometry or spatial configuration may be established. For instance, the regular spacing of the rotational components of the CO₂ bands proves that it is a linear molecule. Similarly it has, in the instance of the water molecule, been possible to compute the angle at the O atom between the bonds connecting it to the two hydrogens.

Band spectra are important for the identification of isotopes and, hence, are useful in the detection of rare products from reactors. The isotope effect, due to the presence of Cl³⁷ along with Cl³⁵, was first observed by Imes³ and later demonstrated under high resolution by Meyer and Levin.¹⁸ The isotope effect is very large in the instance of deuterium substitution for hydrogen because of the large effect on the reduced mass of doubling the mass of one of the component atoms. It is of interest to compare the positions of the ν_2 and ν_3 fundamentals of H₂O and D₂O. The wave numbers are as follows:

	H ₂ O	D ₂ O
ν_2	1595	1179
ν_3	3756	2789

This has interesting possibilities for analytical procedures where a region of interest might be obscured by the presence of water or in certain instances its use as a solvent.

A final statement concerns the astrophysical significance of band spectra. The subject is a timely one because of the large-scale effort currently devoted to space programs, including the utilization of rocket-borne instrumentation and balloon-supported observing platforms. Since only optical radiant energy is a requirement without the necessary possession of the emitting sample, spectra may be used for a study of the atmospheres of planets or envelopes of stars. It is in this way that the presence of ammonia and methane in the atmosphere of Jupiter has been demonstrated. A detailed presentation covering the atmospheres of planets is to be found in a compilation edited by Kuiper.¹⁹ For more up-to-date information on this subject, reference is made to the proceedings of the Twelfth International Astrophysical Symposium that was held at the University of Liege, Belgium, in 1963.²⁰

BATTERIES

The term "battery" generally denotes an assembly of one or more electrochemical cells which exhibit a voltage difference between their two electrodes, so that they will deliver usable current when connected to an external circuit. Some authorities apply the term "galvanic" or "voltaic" cells to this family, to distinguish them from cells to which current is fed from an outside source for purposes such as electroplating or extraction of metals. There are many ways in which a voltage difference can be produced in an electrochemical cell. The simplest cell, thermodynamically speaking, is the "concentration cell" in which electrolyte or electrode materials are incorporated into half-cells in differing concentrations; a "half cell" is a system involving an electrolyte and a single electrode. When the half-cells are connected, the free energy change accompanying the transfer of one substance from high to low concentration results in the liberation of electrical energy. Concentration cells, though interesting theoretically, are not important commercially.

The majority of economically important cells consists of two dissimilar electrodes of metal or metal compounds, immersed in an aqueous solution of an acid, base, or in some cases a salt. The negative of a fresh cell is typically in the metallic state, while the positive is usually an oxide, or occasionally, a salt of the metal. During discharge, the negative electrode is oxidized as electrons leave it via the external circuit, and the positive is reduced. Since by definition an anode is an oxidation electrode, in the literature the negative is generally called the "anode" and the positive the "cathode"; this conforms to accepted electrochemical terminology, though it is the cause of some confusion.

Theoretically, galvanic cells might look more attractive than heat engines as sources of electric power, since the energy changes are not subject to the limitations of the Carnot cycle. In actuality, however, the cost of public-utility-produced power is 3¢ to 5¢ per kWh, as compared with roughly \$2 per kWh for the power delivered throughout the life of a sealed rechargeable nickel-cadmium cell, and \$50 per kWh for a non-rechargeable Leclanché flashlight cell. This is because of inefficiencies in electrochemical operation, high material costs, high cost of the tightly controlled production operations necessary, etc. Galvanic cells have grown in importance because of the strength of other needs such as the need for a portable supply of power, for power at a place far distant from the prime power source or at a different time than can be supplied by the prime source, for a reserve supply of power to cover peak demands which are beyond the capacity of the prime source or to supply power in the event of failure of the prime source. There are also needs for a source of pure direct current or for a stable reference voltage which are filled by galvanic cells.

Taking the familiar lead-acid storage battery and the conventional Leclanché flashlight-type

cell as examples, cell systems are schematized in the literature as follows, the vertical lines denoting phase boundaries between the solid active materials and the electrolyte:

Abbreviations denoting the state and the concentration of the materials may appear beside the chemical symbols. Some cells are shown as containing more than three phases; e.g., those with different electrolyte at each electrode. In all cases, the oxidation electrode, the negative, is given on the left, and the reduction electrode on the right, with the electrolyte phase or phases between. Cell reactions are written in the conventional chemical fashion, the charged reactants on the left and the discharged products on the right. For example,

References which discuss cell reactions in any detail will include also the half-cell reactions for each individual electrode.

The basic thermodynamics of a galvanic cell operating reversibly at constant temperature and pressure is described by the equation

$$\Delta G = -nF\xi \quad (1)$$

where ΔG is the change in the Gibbs free energy, n is the valence change in the cell reaction, F is the Faraday (96,487 coulombs), and ξ is the reversible emf of the cell. In terms of ΔH , the heat of the reaction,

$$\xi = -\frac{\Delta H}{nF} + T\left(\frac{\partial \xi}{\partial T}\right)_p \quad (2)$$

where T is the absolute temperature, and the derivative is the voltage-temperature coefficient of the cell at constant pressure.

Expressing the basic cell reaction as

a practical expression for ξ may be written:

$$\xi = \xi^0 - \frac{RT}{nF} \ln \frac{(\alpha_{\text{L}})^v (\alpha_{\text{M}})^w}{(\alpha_{\text{A}})^x (\alpha_{\text{B}})^y} \quad (4)$$

where R is the gas constant, α_z the activity of species Z and ξ^0 is the standard emf; the latter term, ξ^0 , may be expressed as

$$\xi^0 = \frac{RT}{nF} \log K \quad (5)$$

where K is the equilibrium constant of the cell reaction. Alternatively, ξ^0 may be calculated in terms of the oxidation potentials of the negative and positive electrodes; the potentials of many electrode reactions may be obtained from standard sources.¹ A rough calculation of ξ may be made by using the concentrations of the several species as approximations of their activities; the

activity of a pure phase, such as a solid, is considered to be unity.

In actual operation, a discharging cell does not behave reversibly, and therefore does not obey Eq. (1). Hence it is useful to define the electrochemical efficiency ϵ as the ratio of the chemical energy expended to the electrical energy delivered during the time t_D necessary to completely discharge the cell; i.e.,

$$\epsilon = - \int_0^{t_D} \xi_D i_D dt / \Delta G \quad (6)$$

where ξ_D in this case is the cell terminal voltage, and i_D the current, during discharge. With rechargeable cells, it is also useful to define the storage efficiency ϵ_s as the ratio of the energy delivered during discharge to that returned in the subsequent recharge (denoted by subscript C); i.e.,

$$\epsilon_s = \int_0^{t_D} \xi_D i_D dt / \int_0^{t_C} \xi_C i_C dt \quad (7)$$

In the definition of ϵ_s , it is assumed that the cell is charged until it is returned to its original condition.

Both ϵ and ϵ_s are considerably less than unity in practical operating cells, for a number of reasons. Not all the current that theoretically could be delivered by the quantity of active material in the cell will actually be produced, due to incomplete chemical reactivity, imperfect electrical contact between the active material and the conductive grid, and other factors. Further, observed cell voltage will be less than that predicted from thermodynamic data, due to competing reactions occurring spontaneously within the cell and to "polarization" effects (polarization is the term given to any process, such as the accumulation of products of the discharge reaction at the reaction sites, which causes a reduction in the potential of an electrode as current is being passed through it).

Typically, ϵ will range from 75 to 90 per cent (the latter figure pertaining to alkaline cells with low internal resistance, operating at low discharge rates); ϵ_s will generally range from 55 to 75 per cent, depending, as one factor, on the rate at which charging is done and the consequent spread between charge and discharge voltage. With practical cells, the degree to which the change in free energy of the cell reactants can be realized in terms of electrical energy is not of as much importance as is the electrical energy produced per unit weight or unit volume of the cell.

For the sake of providing some comparison between galvanic cells and thermal converters, consideration might be given to thermal efficiency. This can be approximated by substituting ΔH for ΔG in Eq. (6). Thermal efficiency in many modern cells is 50 per cent to 80 per cent, as compared with 40 per cent to 45 per cent for the better thermal converters. Thermal converters may, however, be superior on a watt-hour per pound basis, particularly when operated over long periods of time.

Physical Configurations, Plate Types. Cells are commonly made in three basic configurations: cylindrical, rectangular, (sometimes called "prismatic," particularly in Europe), and small disk-shaped "button" cells. Each of these has distinct advantages and disadvantages, and each is made with plates of specialized design, tailored to fit that shape. Cylindrical cells make optimum use of internal volume and contain internal pressures well (a necessity with sealed cells). When assembled into multicell batteries, however, they are wasteful of battery internal volume. Further, they require specialized, and often costly, production techniques. Plates for cylindrical cells are frequently molded as slugs of the desired cylindrical shape, or they may be cut from sheet material into long strips which then are rolled, with an intervening strip of separator, into a coil. This sheet plate material may be made by a wide variety of methods including sintering, electroplating, pasting of active materials onto some suitable support, impregnating active materials into a porous matrix, or forming sheet metal. In rare cases, flat rectangular plates may be assembled into a cylindrical cell container.

Rectangular cells are easily assembled; the cases are easily fabricated of a variety of materials. They make acceptable use of battery internal volume. They do not, however, contain well the force of plate expansion or internal gas pressure. And usually a lesser proportion of cell internal volume can be filled with plate material than can be done with cylindrical cells. Button cells lend themselves to automatic production techniques; the assembly operations are relatively simple and inexpensive; the cells are easily stacked into batteries of any required voltage. As disadvantages, they do not contain internal pressures well; they cannot easily be made in sizes much larger than 1.0 ampere hour in capacity; and they involve considerable waste of cell internal volume. Plates for both rectangular and button cells are almost invariably flat. Button cell plates are usually molded or stamped from sheet stock into the required disk shape. Plates for rectangular cells may be sheet material made by any of the methods given in the previous paragraph. Or they may be cast or molded.

"Primary" and "Secondary" Types. Galvanic cells of commercial importance fall into two classes, "primary" and "secondary." Primary cells are said to be nonreversible: at the end of discharge, the active materials are in such state that they cannot be returned to their original condition by charging. Secondary cells are said to be reversible; they can be recharged by applying current to the cell terminals in opposite polarity to that produced by the cell during discharge. As normally used, these cells are not truly reversible in the thermodynamic sense: keeping charge-discharge times within acceptable limits, it takes considerably more than an "infinitesimal increase" in opposing force to drive the cell reaction in the opposite "charging" direction. Ordinarily, primary cells yield higher energy densities (ratios of power output to weight or volume) than

do secondary cells. One reason for this is that providing rechargeability involves considerable sacrifice in the amount of reactive material that can be packed into a given unit weight or volume, due to the need to incorporate relatively massive grid structures within or around the plates, plus space- and weight-consuming separators between the plates. Providing rechargeability may even require incorporating the active materials in a form which offers less than optimum electrochemical reactivity.

Primary Cells. Until recent years, zinc was used as the anode of almost every primary cell known. The metals above zinc in the electromotive series (aluminum, magnesium, calcium, potassium, etc.) react so readily with the water of the aqueous electrolytes (the only electrolytes judged practical in the past), that much of their energy is consumed in wasteful side reactions. The metals below zinc provide inadequate cell voltage and, in several instances, are costly (chromium, cadmium, cobalt). Zinc is still the only common primary anode, although magnesium, calcium, lead, silver, and indium have been used for some special military and experimental cell types. A considerably greater variety of materials has been used as cathodes, including, in the older cells, manganese dioxide, oxygen, cuprous oxide and copper, carbon, and mercuric oxide. More recently, primary cells have been built with cathodes of mercuric oxide, silver (I) and silver (II) oxide, lead dioxide, zinc chloride, lead chromate, copper halides, silver chloride, and, in experimental cells, such materials as bismuth trioxide, vanadium pentoxide, and a variety of organic compounds such as the nitrobenzenes, nitropropanes, and N-halogens which promise high energy yield per unit weight.

Secondary Cells. Far fewer secondary than primary systems have been developed to a practical level. The difficulties in providing acceptable cost, satisfactory physical, electrical, and environmental characteristics, together with rechargeability, are so severe that today there are only six secondary systems of any practical importance. Five of these—the nickel-cadmium, nickel-iron (Edison), silver-zinc, silver-cadmium, and zinc-manganese dioxide—are alkaline. (In Europe, particularly the Soviet Union, another alkaline system, the nickel-zinc, is used.) The remaining system, the familiar lead-acid, is the cheapest storage battery type, and is by far the most important commercially. Total sales of all secondary types in 1962 were reported to be \$460 million; of this, \$425 million was for lead-acid batteries, the preponderant majority of which were ordinary car or truck starting batteries.

Standard Cells. Standard cells are galvanic cells that are used to provide a stable, known voltage for calibration of other equipment, rather than for supplying electric power. The only type in general use now is the "Weston," or mercury-cadmium cell. The "saturated" cell type is: $\text{Cd} | \text{Hg}_3\text{CdSO}_4 \cdot 8\text{H}_2\text{O} | \text{CdSO}_4 | \text{Hg}_2\text{SO}_4 | \text{Hg}$. The anode is a 10 per cent cadmium amalgam; the

CdSO_4 is a saturated aqueous solution. The emf at 20°C is 1.01864 volts. It has a fairly large temperature coefficient (0.00004 volt/ $^\circ\text{C}$ at 20°C). A more generally used type, the "unsaturated" cell (assembled without cadmium sulfate crystals) has a temperature coefficient of 0.00001 volt/ $^\circ\text{C}$.

Fuel Cells. Fuel cells, though operating as galvanic cells at the electrodes, are in a class by themselves in that they provide direct, single-site conversion of original raw materials into electrical power, obviating the boiler-turbine-transmission-rectifier chain that precedes the production and use of ordinary batteries. The raw materials, usually involving hydrogen and oxygen, are fed into the cell in a constant flow, as long as power is needed; when the fuel flow is stopped, the cell is inert. The fuels react at the electrodes, forming H_2O as the exhaust in most cells, and liberating electricity. Calculating actual power output versus theoretical free energy change of the original fuels, efficiencies of 65 to 85 per cent have been achieved in prototype and laboratory models. The technological problems remaining to be solved before practical fuel cells appear on the market are formidable, and include elimination of the water from the pores of the electrodes, preventing contamination of the electrochemical system by impurities carried in with the cheaper fuels, achieving workable energy densities, simplifying the necessary control and supporting equipment, and providing adequate electrode life. For an excellent general discussion of various fuel cell types, see reference 2.

BETATRON

The betatron is a particle accelerator using a sustained induced voltage to accelerate the particles to full energy during the whole period of acceleration of the particle. Since this method of acceleration seemed most applicable to electrons, the name "betatron" was used to indicate that it was the agency for producing high-speed electrons. The action of the betatron is similar to the action of an electrical TRANSFORMER in which a high-voltage winding of many turns is used. In a transformer, the voltage can be stepped up from the primary voltage, V_1 , to the secondary voltage, V_2 .

$$V_2 = V_1 N_2 / N_1$$

where N_2 is the large number of turns of the secondary and N_1 is the small number of turns in the primary. For example, x-ray transformers having high voltage, such as 100,000 volts, have very many turns of fine wires and consequently raise the primary voltage by a large factor.

The main structure of the betatron is really a transformer, and focusing magnets are arranged around the transformer core where a secondary winding might be put. A vacuum tube instead is placed between these focusing magnets so that it can conduct electrons hundreds of thousands of times around the core. Each time the electron circulates around the core it acquires an energy equivalent to the voltage which would have been induced in one turn of wire at that instant.

In order to guide the electrons on many revolutions the focusing magnet can be such that the magnetic field decreases with increasing radius. Then the lines of force bulge outwardly about the orbit, providing vertical focusing forces back to a horizontal orbit in case the particle strays above or below the orbital plane. This bulging field is the requirement for vertical focusing, and it is used in cyclotrons too. However, it is necessary that the magnetic field decrease less rapidly than $1/r$, where r is the radius of the orbit. If this latter requirement is met, then radial focusing will be insured; because the required centripetal force to hold the particle in the circle going around the core decreases as $1/r$. Consequently, if the magnetic force decreases less rapidly than this, it will be too strong at large radii to permit the orbit to remain circulating at a large radius, and it will be too weak at small radii to maintain the particle circulating at a small radius. The particle thus will hunt about the so-called equilibrium orbit by means of this radial focusing action in addition to the previously mentioned vertical focusing action. The oscillations of the particle about this orbit are called betatron oscillations, and the name appears in the scientific literature referring to particle motions in other accelerators such as synchrotrons, because this focusing was first worked out for the case of the betatron.

It is possible to have strong focusing magnets with much more rapid variation of field with radius to provide the focusing. In this case, a succession of focusing and de-focusing magnets must be used which alternately focus vertical and radial motion and which are called alternate gradient focusing magnets. Such strong focusing magnets can limit the oscillation of the particle about the equilibrium orbit to a very small amplitude.

The usual betatron has a magnetic field which rises proportionately with the increase in the transformer's magnetic flux within the orbit. By means of this proportionality, the strength of the guiding field rises along with momentum gained by transformer action, and hence the guiding field provides sufficient centripetal force to hold the particle at the same radius.

The first betatron of this type produced 2 MeV and radiation equivalent to 2 grams of radium.

It is now in the Smithsonian Museum in Washington, D.C. This accelerator is the size of a typewriter. The largest betatron can generate beams of 320 MeV. The x-rays and electrons can be used to produce mesons and numerous nuclear disintegrations. The most commonly used betatrons are for 25 to 35 MeV. These provide x-rays of maximum penetration in iron for industrial radiography, and they provide x-rays and electrons with optimum depth dose characteristics for x-ray or electron therapy of the human body.

The intensity of radiation from the 25-MeV betatron is of the order of 100 to 200 roentgen/min at a meter from the target for x-rays. With the extracted electron beam, the ionization doses would depend on how widely the electrons are spread at the point of treatment, but comparable doses are obtained. The large 320-MeV betatron at the University of Illinois produces intensities of the order of 20 000 roentgen/min at a meter or, in other terms, of the order of 5 watts.

It is possible to make what are called fixed-field alternating-gradient betatrons (FFAG). In this case, the focusing field is constant in time, and the particle orbit can be caused to spiral either outwardly or inwardly with increasing energy between the focusing poles of a direct current magnet or a permanent magnet. These FFAG betatrons are capable of giving a beam of x-rays up to 20 per cent of the time, whereas the betatrons with time-varying focusing fields just give one pulse of electrons in every cycle, and these pulses are only of the order of a microsecond in duration. Because of the large duty factor available with FFAG betatrons, it should be possible to achieve intensities of 10,000 watts. Although FFAG combination betatrons and synchrotrons have been made, full advantage has not yet been taken of a large duty factor achievable by incorporating a full-size transformer core within the betatron orbit.

In the case of the conventional betatron with constant orbit radius, the relation between the strength of guiding field and the total flux change within the orbit can be found as follows:

The momentum of the orbit

$$p = \frac{e}{c} BR$$

while the rate of change of momentum

$$\frac{dp}{dt} = eE$$

where e is the charge of the electron, c is the velocity of light, B is the magnetic field in gauss, R is the radius in centimeters, and E is the electrical field in electrostatic units.

$$2\pi RE = \frac{1}{c} \frac{d\Phi}{dt}$$

the volts per turn where Φ is the flux linking the orbit. Combining the last two equations

$$\frac{dp}{dt} = \frac{e}{2\pi Rc} \frac{d\Phi}{dt}$$

Thus, after a lapse of time

$$p = \frac{e}{2\pi Rc} (\Phi_2 - \Phi_1)$$

Combining this with the first equation

$$2\pi R^2 B = \Phi_2 - \Phi_1$$

Thus the flux change within orbit $\Phi_2 - \Phi_1$ is twice as big as the flux would be if the flux density, B , were constant within the orbit. Therefore, the transformer core must be adjusted so that the proper excess flux density provided within the orbit meets the conditions of this last relation if the orbit is to be at a constant radius, the assumption made in the above derivation.

BIONICS

Bionics is defined as the branch of knowledge pertaining to the functioning of living systems and the development of non-living systems which function in a manner characteristic of, or resembling, living systems. The definition of bionics infers the use of scientific skills and techniques from biological, physical, mathematical, and applied sciences in carrying out research in which: (1) the functions of chosen biological components and systems are studied and analyzed to determine underlying principles and processes that may lead to methods for improving physical components or systems, and (2) the theories and techniques of chemistry, physics, and mathematics are applied to advance our knowledge of the principles upon which these functions are based.

Bionics research depends on the acceptance of certain postulates. These postulates are of two types—one essentially operational, the other essentially technical. The important operational postulates are: (1) common experience shows that biological systems, for example the human nervous system and its peripheral equipment, perform operations such as pattern recognition and identification, discrimination, and learning that no non-biological system can now perform efficiently; (2) other biological components perform such functions as detection, filtering, and information transfer more efficiently and with greater certainty over broader bandwidths than do present non-biological components; (3) intensive study, analysis, and application of the principles that make superior biological performance possible can lead to non-biological systems that equal or may, in some cases, exceed biological systems capabilities. The technical postulates are: (1) The functional advantages of biological systems are implied in the unique methods for information transfer, memory storage, and retrieval, united with unique ways for correlating and integrating data from many

sensors or sensor systems. These unique methods depend mainly on: (a) many converging and diverging information transfer channels and many connections between channels, and (b) the special properties of biological components at the points where these channels are interconnected. (2) The superior capabilities of biological components or particular elements of the components (for example, receptor cells or nerve muscle junctions) are derived from specific ways of interconnection and probably as well from specific molecular properties. (3) Analysis and study of the relevant data describing biological systems that will represent major improvements over existing physical and engineering hardware. (4) The present rapid advances in microminiaturization techniques suggest that, for the first time, the possibility exists for the development of physical components or systems that incorporate these superior biological principles and processes.

The definition of Bionics suggests the methodology of procedure. We design, grow, or in some way obtain non-biological systems that function in a way "resembling" living systems. The physical component simulates the biological way of doing or carrying out its function. To obtain this objective, we first choose the biological components that perform the desired function; second, we compile the descriptive biological data; third, we translate this data into engineering terms; and fourth, we apply the translated data for the physical simulation of the function.

This process requires application of relevant mathematics to describe clearly, and as rigorously as possible, the biological function by some mathematical theory or model. This process may also require various techniques from the physical sciences to arrive at the necessary data defining the biological function of interest.

While the bionics research procedure requires the description, mathematically, of the function to be performed by the non-biological system, it may also require mathematical and physical descriptions of the properties of the materials used to construct the non-biological analog.

Gaining enough data to describe the given biological function may require study of the biological component or one of its elements at the molecular level. Similarly, solid-state or molecular techniques may be required to construct the physical system that is the appropriate simulation of the desired biological function.

Successful bionics activity may be modified by several factors. These include the complexity of the biological functions; the kind, quality, and quantity of data available to describe the functions; and the existence of relevant mathematical and physical techniques essential to the simulation of the functions.

In terms of the bionics objectives, the scope of the work must include research on the following components and/or systems:

- (a) receptors or sensors;
- (b) receptor systems—including central interconnections and interconnections among receptor systems;

- (c) central nervous system networks and the interconnections among parts of the nerve network;

- (d) effectors and actuators;

- (e) effector systems—including the feed-back and feed-forward connectors to and from the central processor;

- (f) the integrated system made up of sensors and their input channels, the central correlating, control, and computing networks, and the channels from the central system to the effectors and actuators.

This complete research program will extend over a long period of time. However, progress has been made. Data have been acquired, analyzed, and put into engineering terms to provide a set of specifications for the functional properties of several types of neurons. The neuron is presumed to be that physiological component underlying observed psychological parameters such as learning, adaptation, etc. Therefore, the construction of a network of artificial neurons should, to some extent, simulate these observed behavioral parameters. In addition, data have been acquired and analyzed from the field of experimental psychology on functions such as learning. These data can be translated into engineering and can suggest types of components which can simulate the learning function directly. This example illustrates a procedure which is common in bionics research. One can start at the operational level with an observed set of functional parameters and attempt to synthesize the class of mechanisms that could simulate these functions, or one can start with the biological component which is presumed to give rise to these functions and attempt to simulate this component. The choice of one method over the other depends greatly on the assurance one has of the validity of the data at one level or the other.

BIOPHYSICS

Just as biochemistry was born slowly and painfully out of general physiology over a period of fifty years centered at the turn of the century, so biophysics is now emerging as a major, distinguishable part of science. Disciples of this youngest daughter of general physiology, biophysicists apply the new and developing techniques of physics and physical chemistry to biological subject matter; in addition, they develop new methods to examine, and theories to describe, biological processes.

Because of its biological and physical origins, the subject cuts into, or overlaps with, several other "branches" of science. However, like all these other disciplines, the boundaries are not too well defined, nor can they be in a classification which is essentially a subjective one. The various subdivisions of biophysics—mathematical, physical, physicochemical, physiological and psychological—intrude on and overlap with the corresponding established disciplines whenever those disciplines make a physically oriented attack aimed at the fundamental description and understanding of living matter.

Certain men in history focused the experience of their time. Biophysics might be said to have begun immediately after Isaac Newton was hit on the head with the falling apple: effects of gravitational attraction and the psychological results of the impulse to his head doubtless drew his immediate attention! Interest in impulse and momentum-transfer to living matter persists for obvious pathological reasons.

The discovery of animal electricity by Luigi Galvani in 1778 opened up, in Alessandro Volta's words 20 years later, "a very wide field for reflection." The development of electrophysiology and the more fundamental biophysical studies of the molecular and ionic mechanisms associated with irritability of tissue are a distant consequence.

The anatomist, Adolph Fick, considered by some to be the father of biophysics, showed the way to quantitative studies of diffusion and mass transport. Recognizing immediately the interdisciplinary nature of his studies, he thoughtfully published his work simultaneously in a journal of physics and a journal of physiology in 1855. Modern familiarity with exchange processes, membrane processes and the like, stems from his pioneering work. Meanwhile Thomas Young was completing a long career during which he

formulated important ideas on the physics of color vision and heart action. Young was followed later into studies on these and many other topics of biophysical interest by one of the intellectual giants of the nineteenth century, the ubiquitous scientific explorer, Hermann Ludwig Ferdinand von Helmholtz, who put color vision, hearing, and energy conversion, on a physical foundation which was firm enough to withstand nearly a century's further progress.

The basic principles of fluid flow through blood vessels, and pipes in general, were described quantitatively in 1884 by Jean Louis Poiseuille. It was only a few years later that that last fruitful quarter-century was completed in rousing fashion by three other discoveries which were to lead to later very important developments in biophysics. First, Svante Arrhenius, Hans Kohrausch, and others characterized the electrical and osmotic properties of *ionic* solutions. Second, Henri Becquerel discovered natural radioactivity in 1895; and third, Wilhelm Roentgen discovered the penetrating and ionizing radiation which he named x-rays in 1898. From the new fundamental knowledge of electrolytes, have proceeded electrochemical studies on the origin and nature of electric currents in living tissue, and studies on the subtleties of water balance in cells and tissues. In a similar development, further knowledge of the origin, physical properties and the physical effects of particulate and electromagnetic ionizing radiations has formed the basis for studies of their biophysical effects, which are closely interwoven with those being studied in radiation chemistry, radiobiology and radiology. For example, studies on the time and spatial distribution of the energy absorbed by living tissues from gamma-ray beams have led to some understanding of the mechanisms of (a) changes induced in mass-transport processes in blood plasma, (b) changes in chemical reactivity, and (c) subtle changes in the electrochemical processes which form the basis of transmission of information along nerve membranes. The psychological effects of an increased background of ionizing radiation on the noise level in human nerve transmission may be one of man's important problems in the future.

The continuing development of fast, sensitive electronic equipment—fast dc amplifiers, electron microscopes of high resolving power, ultraviolet microscopes, mechano-electrical transducers, etc.—has encouraged more and more physicists to become interested in the properties of biological material. Conversely, students of biology have become increasingly more familiar with properties of fundamental particles, physical measurements, kinetic techniques and analyses, etc., and are applying them to their focus of interest when feasible. For instance, during the 1930's some very clever experimental and theoretical studies were begun by A. V. Hill and others on the transformation of the energy from chemical reactions into the mechanical energy of muscle contraction and the attendant electrochemical energy for nervous control. Although

the process is unbelievably complicated on the molecular scale, research is now able to be centered on myosin, the remarkable contractile protein-enzyme molecule, and its molecular associate, actin. Chemical activity of myosin as a specific hydrolytic enzyme is accompanied by conformational changes, which permit both sliding and folding processes to occur at the macromolecular level during contraction of the bulk muscle. The energy balances (heat, mechanical, electrochemical, chemical) and the power balances are slowly being worked out in detail. They are devious, reflecting the complexity of the basic molecular system. Although still only partly quantitative, a comprehensive molecular theory is becoming more and more satisfying.

Since the early 1950's, a concerted study of the interaction of matter waves (sound and ultrasound) with living tissues has been apparent, with contributions from several disciplines: electrical engineering studies on the production, focusing and measurement of radiated sonic energy; physiological studies on the reception by the ear and other mechano-receptors; electrochemical studies of interfaces irradiated with acoustic beams, associated with the receptor-nerve junction; physical studies of the mechanisms of absorption by watery polymeric solutions. From these has emerged a flourishing part of biophysics not only concerned with the fundamental processes of absorption and transduction, but also providing knowledge useful in the diagnosis and location of brain disorders and subcutaneous lesions, and even therapy by acoustic irradiation.

A mathematical description of selected biophysical concepts was made in 1938 by Nicholas Rashevsky, and in the years since, he and one group of biophysicists have been actively developing mathematical descriptions of current ideas on growth, cancer, energy and mass transfer in cell respiration, cell movements and, more recently, nerve conduction and the stability (steady-state) of living organisms (see MATHEMATICAL BIOPHYSICS for Rashevsky's account of this research). Inherent in this work are developments of new mathematical concepts, or algebraic models, which at least in principle can describe the detailed behavior of living tissue when stimulated with certain forces. Perhaps the greatest contribution of this kind of work is that it presses the experimental biophysicist continually to refine his techniques, to measure yet more parameters of the living material he is studying, for the models developed usually contain explicit functions of parameters which are not or cannot yet be measured. The difficulty in this work is to be able to relate the theory, at sufficiently small intervals in its development, to reality as found by the experimentalist.

The quantitative concepts so successfully used in the electrical and electronic engineering of guided missiles have recently been applied with useful results to processes occurring in the brain, and to the better understanding of the principles of organization of the physical apparatus which

forms the physical basis of memory, emotions, and instinct. Even without complete knowledge about how a neuron works, in terms of atoms and molecules of which it is composed, certain properties of cell assemblies, or neural nets, are beginning to show in research on electronic models, and the systems concept is suggesting where else we should look for other properties of other subsystems, or assemblies. This biophysical approach may, in another twenty years, enable man to give a better physiological as well as psychological account of neuroses and anxieties. Maintenance of the steady-state, assessment of the kind of and time of response to given inputs or feedbacks—in short, problems in stability of the system—occupy an important group of biophysicists today. Even the teaching of biophysics has received benefit from the early introduction of the systems concept into the course: it is a good framework on which the teacher can hang the details of the course.

Meanwhile a considerable number of biophysicists concern themselves with two very new and modern topics: molecular biophysics and the biophysics of weightlessness. This work seems to have to be done by big teams, in which the biophysicist has his role. Evidence was presented in 1961 that a coding of genetic and hereditary information in the chromosome may be carried in the arrangement of the four pyridine and pyrimidine bases which occur in desoxyribonucleic acid (DNA), and since then other macromolecules have become suspect. Further on macromolecules: for many years certain vague variants of composition and structure had been associated with specific so-called molecular diseases. As a result of these two developments, the subject of "molecular biology" has become loosely circumscribed as a special very important interest in science; and as part of this circumscribed interest has sprung "molecular biophysics"—loosely (yet) defined as the study of structure and physical properties of macromolecules as they affect their physicochemical roles in living tissue.

With man now entering the space age, the problems he and his living ancillary equipment will have to face are already becoming apparent. Lessening of elasticity in the major arteries of the astronauts—an accommodation to less stress on the walls in the absence of gravitational force—has recently been proven, and its mechanism is being sought. Plant cells fixed and stained in space showed distortions of the cell membranes, as well as disorder in the normally well-organized nucleus, mitochondria, and other cell components. The absence of gravitational force apparently has new and unpredictable effects on heretofore earthbound biological material. It probably should be mentioned in passing that we can only guess now about what changes will occur in living tissues as they leave the electromagnetic field of the earth with which so many biological rhythms seem to be bound.

In the words of A. V. Hill, biophysics is the study of biological function, organization and

structure by physical and physicochemical ideas and methods. The application of techniques and fundamental principles in studies of living tissues and the recognition of new principles and the development of new methods from them comprise biophysics.

An International Union of Pure and Applied Biophysics recognizes the scope of the subject, and many countries have national Biophysical Societies. Learned journals devoted to research, and review papers in biophysics include: *Advances in Biological and Medical Physics*, *Progress in Biophysics and Biophysical Chemistry*, *Biophysical Journal*, *Acta Biophysica*, *Physics in Medicine and Biology*, and *Archives in Biochemistry and Biophysics*. The *Proceedings of the Institute of Electrical and Electronic Engineering* has had notable issues on biophysical topics. Among the contributed volumes designed to broaden the view of the specialist is "Biophysical Science—A Study Program," edited by J. L. Oncley *et al.*, John Wiley & Sons, Inc., New York, 1959.

Textbooks at various levels of study, and reflecting the individual authors' experience and viewpoints of this broad and not too well-defined interdisciplinary subject include: "Biophysical Science," by E. Ackerman, Prentice-Hall, Inc., Englewood Cliffs, N.J., 1962; "Biophysics—Concepts and Mechanisms," by E. J. Casey, Reinhold Publishing Corp., New York, 1962; "Molecular Biophysics," by R. B. Setlow and F. C. Pollard, Addison-Wesley Publishing Co., Inc., Reading, Mass., 1962; "Mathematical Biophysics. Physico-mathematical Foundations of Biology," by N. Rashevsky, 3rd Revised Edition, Vol. I, Dover Publications, Inc., New York, 1960.

BOLTZMANN'S DISTRIBUTION LAW

Let us consider a system composed of molecules, of one or more kinds, able to exchange energy at collisions but otherwise independent of one another. Evidently we cannot say anything useful or interesting about the state of a particular molecule at a particular time. We can however make useful statements about the average fraction of molecules of a given kind in a given state, or, what is the same thing, the fraction of time spent by each molecule of a given kind in a given state. If the system is maintained at a definite temperature, for example by keeping it in a thermostat, then the fraction of molecules of a given kind in a given state is determined by the energy of this state and by the temperature. In particular if we denote by i and k two completely defined states of a molecule of a given kind and by E_i and E_k the energies of these two states then the average numbers N_i and N_k of molecules in these two states are related by

$$N_i/N_k = \exp \{ -\beta(E_i - E_k) \} \quad (1)$$

where β is a parameter having a positive value determined entirely by the thermostat; i.e., β has the same value for all states of a given kind of molecule and for all kinds of molecules. In other words β has all the characteristics of temperature except that it decreases as temperature increases. If we write

$$\beta = 1/kT \quad (2)$$

then it can be shown that T is identical with thermodynamic (or absolute) temperature and k is a universal constant whose value determines the unit of T called the degree. When k is given the value 1.38041×10^{-23} joules/degree, the temperature scale becomes the Kelvin scale defined by $T = 273.16^\circ\text{K}$ at the triple point of water. Substitution of Eq. (2) into Eq. (1) leads to

$$N_i/N_k = \exp \{ -(E_i - E_k)/kT \} \quad (3)$$

This fundamental relation is called Boltzmann's distribution law after the creator of STATISTICAL MECHANICS, Ludwig Boltzmann, (1844/1906) Professor of Physics in Leipzig, and k is called Boltzmann's constant (see also KINETIC THEORY).

We must now discuss the meaning of the words used above, "completely defined state." These words have one meaning in classical mechanics and a different, but related, meaning in quantum mechanics. Since the quantal definition is the simpler we shall discuss it first. We begin by considering a system of highly abstract "molecules" having only a single degree of freedom, for example linear oscillators. The quantum states form a simple series specified by consecutive integers called the quantum numbers. In this simple example there is no ambiguity in the meaning of "completely defined state"; each state i is completely defined by the integral value of a single quantum number. Let us now consider a "molecule" with three degrees of freedom such as a structureless particle moving in three-dimensional space. The complete specification of this particle's state requires not one but three integral quantum numbers. If the particle moves freely in a cubical box, the three quantum numbers may be associated with motion along the three directions normal to the faces of the box. The subscript labels i and k in the previous formulas are abbreviations for sets of three quantum numbers. For example i might mean (2, 5, 1) and k might mean (3, 4, 2). There can now be several states having the same energy. For a particle moving freely in a cubical box, it follows from symmetry that the states (2, 5, 1), (1, 2, 5), (5, 1, 2), (1, 5, 2), (2, 1, 5), and (5, 2, 1) all have the same energy; such an energy level is called sixfold degenerate. (One should *not* speak of a p -fold degenerate state, but of a p -fold degenerate energy level.) It is sometimes desirable to consider the fraction of molecules having a given energy rather than the fraction in a given state. If N_i and N_k denote the average number of molecules of a given kind having energy E_i and E_k then evidently

$$N_i/N_k = (p_i/p_k) \exp \{ -(E_i - E_k)/kT \} \quad (4)$$

Alternatively, if f_i denotes the average fraction of

molecules of a given kind having energy E_r , then

$$f_r = p_r \exp(-E_r/kT) / \sum_s p_s \exp(-E_s/kT) \quad (5)$$

The sum \sum_s occurring in the denominator is called the partition function.

It may happen that certain degrees of freedom are completely independent of other degrees of freedom. We call such degrees of freedom "separable." The partition function can then be separated into factors relating to the several sets of separable degrees of freedom, and Boltzmann's distribution law is applicable separately to each set of separable degrees of freedom. For example, for an electron moving freely in a rectangular box, the translational motions normal to the three pairs of faces and the fourth degree of freedom due to spin are all separable.

We shall now consider briefly the meaning of completely specified state according to classical mechanics. We know that classical mechanics is merely an approximation, sometimes good but sometimes bad, to quantum mechanics. Motion in each separable degree of freedom can be described classically by a coordinate x and its conjugate momentum p_x . If x and p_x are plotted as Cartesian coordinates, the diagram is called the phase plane. There is a simple correlation between the quantal and the classical descriptions: the density of quantum states is one per area h (Planck's constant) in the phase plane. This may be extended to several degrees of freedom. If there are f degrees of freedom, the motion is described by f coordinates q_1, \dots, q_f and the conjugate momenta p_1, \dots, p_f . We can imagine these plotted in a $2f$ dimensional Cartesian space called phase space. There is then one quantum state per $2f$ dimensional volumes h^f of phase space. In the classical as in the quantal description there can be degenerate energy values and there can be separable degrees of freedom. The classical description is a good approximation to the quantal description when the spacing between energy levels is small compared with kT . An example of an effectively classical separable degree of freedom is the motion in a given direction of a free particle. If the linear coordinate is denoted by x and the linear momentum by p_x , then the fraction of molecules at a position between x and $x + dx$ and having a momentum between p_x and $p_x + dp_x$ is

$$\frac{\exp(-p_x^2/2mkT) dx dp_x}{\int dx \int_{-\infty}^{\infty} dp_x \exp(-p_x^2/2mkT)} \quad (6)$$

where m is the mass of the particle so that its (kinetic) energy is $p_x^2/2m$. In the classical treatment, the kinetic and potential factors are separable. Consequently the fraction of molecules, anywhere or everywhere, having momentum between p_x and $p_x + dp_x$ is

$$\exp(-p_x^2/2mkT) dp_x / \int_{-\infty}^{+\infty} \exp(-p_x^2/2mkT) dp_x \quad (7)$$

Equation (7) is called Maxwell's distribution law

after Clerk Maxwell (1831/79), Professor of Physics at Cambridge (England), who obtained it in 1860 before Boltzmann in 1871 obtained his wider distribution law. Maxwell derived his distribution law from the conservation of energy together with the assumption that the motion is separable in three mutually orthogonal directions. The latter assumption was violently attacked by mathematicians, but we now recognize that the assumption is both reasonable and true.

In conclusion we must mention that a necessary condition for the validity of Eq. (3), and consequently of other formulas derived from Eq. (3) is that $N_i \ll 1$ for the state (or states) of lowest energy and *a fortiori* for all other states. When this inequality does not hold, Boltzmann's distribution law must be replaced by a more general and more precise distribution law, either that of Fermi and Dirac or that of Bose and Einstein according to the nature of the molecules.

BOND, CHEMICAL

The chemical bond is a concept used to account for the close association of atoms in neutral or charged molecules. In molecules with more than two atoms, the concept attempts to describe the stability and other properties in terms of the aggregate effect of several bonds. The description of the bonds may then be either *localized*, i.e., confined to attraction between pairs of atoms, or *delocalized*, where the attraction is thought to extend over larger groups of atoms. Various idealized types of bonds are customarily recognized: *ionic* or electrostatic bonds, *covalent* or electron-pair bonds, and metallic bonds.

Ionic bonding exists, e.g., in solid and fused salts. Electrons here are localized in one or the other ion giving rise to charged particles whose mutual attractions and repulsions can be calculated from simple electrostatic theory. Since electrostatic forces do not diminish rapidly with distance, significant interactions still exist beyond nearest ionic neighbors in the crystal lattice. Nevertheless, the *lattice energy*, or the total ionic bonding energy referred to an ideal ionic gas as zero, can be calculated as the sum of the Coulomb energy terms for all possible ion pairs at their equilibrium distances. Empirical corrections for short-range repulsions between electronic envelopes of the

ions must be made, and polarization and van der Waals energies can be taken into account.

Covalent bonding is described qualitatively according to the ideas of Lewis and Kossel as being due to the sharing of electron pairs between bonded atoms. The valence-bond treatment of Heitler and London, elaborated by others, applies quantum mechanical theory to this idea. Approximate wave functions for bonding electron pairs are constructed as products of atomic wave functions. The energy of the covalent bond, referred to the isolated atoms as zero, can then be calculated. A major portion of this energy is the quantum mechanical *exchange energy*, which arises from the fact that either electron may reside on either atom with equal probability.

In certain molecules, e.g., benzene, two or more plausible pairing schemes can be combined in the same calculation; bond energies calculated this way indicate molecular stability is enhanced by the so-called *resonance energy*.

Polar covalent bonds, where electron pairs are not shared equally, are described by including ionic wave functions in the calculation. Among chemical substances, one can find a more or less continuous variation of bond polarity, ranging from purely ionic bonds to nonpolar covalent bonds. The polarity of a bond can be judged qualitatively by the electronegativity difference of the bonded atoms.

Alternately, covalent bonds may be described in terms of the molecular orbital (MO) method, in analogy to the description of electrons in atoms by means of atomic orbitals. Electrons are assumed to be delocalized throughout the molecule consistent with the overall molecular geometry, their motion being described by means of wave functions obtained as linear combinations of atomic orbitals (LCAO approximation). Each molecular orbital can accommodate two electrons with opposed spins and corresponds to a certain level of binding energy for the electrons. The most stable electron configuration corresponding to the molecule in the ground state (lowest energy) is then obtained by filling of MO's with electron pairs in the order of increasing energy.

When there are one or more valence electrons per atomic valence orbital, the description can often be reduced to an equivalent series of MO's localized between two atoms, and thus represents conventional covalent bonds. On occasion, some bonding electrons still remain delocalized as in benzene, the boron hydrides, or carbonate ion; in such situations, molecules tend to be more stable than expected from a conventional view as a consequence of the *delocalization energy*. In this context, the delocalization energy corresponds to the resonance energy of the valence bond description. Molecular orbitals may be classified by the symmetry of the electron distribution in them, e.g., as σ bonds (bond direction is an axis of symmetry) or as π bonds (one symmetry plane containing the bond direction). Multiple bonds always consist of one σ bond and one or two π bonds. Another distinction is based on relative energy: a bonding MO has

lower energy than the constituent atomic orbitals, an antibonding MO has higher energy.

In metals where there are commonly few valence electrons per atom, the MO description is completely delocalized. The valence MO's form, on an energy scale, bands of closely spaced energy levels many of which have the same energy (degenerate levels). For lack of electrons, the bands are only partially filled, the electrons are not all paired and are free to move throughout the solid in this so-called conduction band. In semiconductors, the valence band is completely filled but an empty band, slightly higher in energy, can receive electrons by thermal excitation or other energy input, thus becoming a conduction band. Bonding in semiconductors can be viewed as intermediate between the metallic and the covalent type. Graphite, condensed aromatic hydrocarbon derivatives and molecules with conjugated multiple bonds can also be placed in this intermediate category as evidenced by recent research. Examples of bond type intermediate between metallic and ionic are the alloys and interstitial compounds of transition metals and hydrogen, carbon and nitrogen, and perhaps the nonstoichiometric oxides and sulfides of the transition metals.

Properties which have found use in the systematic discussion of bonding are the strength, length, force constant, and polarity of bonds. The strength of chemical bonds is measured in terms of *bond energies* and bond dissociation energies. Bond energies are defined so that the sum of the energies of the bonds broken in completely atomizing a molecule or complex ion is equal to the energy of atomization of the substance. Bond energies depend on the order of the bond and typically range from 30 to about 100 kcal/mole for single bonds, up to about 150 kcal for double bonds and up to about 220 kcal for triple bonds. Bonds of a given type between a fixed atom and a series of other atoms generally decrease in strength as the principal quantum number of the valence electrons of the other atoms increases.

The *bond dissociation energy* is defined as the energy required to break one given bond in a molecule yielding, in general, atoms and/or smaller molecules. Bond dissociation energies and bond energies are identical only in diatomic molecules. Significant differences in more complex cases may occur, particularly when delocalization or resonance is involved in the broken bond, or in the molecular fragments. This implies that the energy of given bond may depend on the environment in the remainder of the molecule. Nevertheless, the concept has proved invaluable in the correlation of molecular structure with thermodynamic and kinetic stability. Bond energies and bond dissociation energies are derived from heats of formation and reaction, activation energies in reaction kinetics, appearance potentials in mass spectrometry, and from electronic spectra.

Bond lengths, or equilibrium internuclear distances, are determined from x-ray, electron, and neutron diffraction patterns, from rotational spectra and the fine structure of Raman and

infrared spectra. They depend on the identity of the bonded atoms and are a function of the bond strength and the bond polarity. Sets of atomic radii have been developed for the various bond types such that radius sums duplicate normal bond lengths. Comparisons of computed and observed bond lengths can thus be made to characterize the bonds. Bond stretching *force constants* are obtained from vibrational spectra and serve as an additional index of bond character. Force constants are a measure of the curvature of the potential energy surface at the equilibrium distance; they increase with bond strength and decrease with bond length.

Bond dipole moments are a quantitative measure of the polarity of bonds and permit calculation of the distribution of charge between bonded atoms, if bond lengths are known. Bond dipole moments are estimated by expressing the molecular electric dipole moment (obtained from dielectric or Stark effect measurements) as the vector sum of the constituent bond moments. This method should be used with caution since nonbonding electron pairs in directional hybrid orbitals may make significant contributions to the molecular moment.

BOSE-EINSTEIN STATISTICS AND BOSONS

Bose-Einstein statistics is a type of quantum statistics concerned with the distribution of particles of a particular kind among various allowed energy values taking into account the quantization of the energy values. Quantum statistics is a branch of STATISTICAL MECHANICS which treats the average or statistical properties of a system composed of a large number of particles using standard mathematical techniques and the properties of the constituent particles. It is different from classical statistical mechanics only in that the particles of the system are described quantum mechanically.

Let us consider a system of N non-interacting particles. Three different distributions of the

particles among the various energy levels are possible depending upon the assumptions that are made about the particles. If it is assumed that each arrangement or distribution which conserves energy is equally probable and also that the particles are distinguishable, and if each permutation of particles among the possible levels is counted as a different distribution, one obtains an average for the relative number of particles in the various levels known as the Maxwell-Boltzmann distribution. If the particles are treated as indistinguishable and only the number of different combinations of particles is counted, the Bose-Einstein distribution is obtained. A third distribution, known as the Fermi-Dirac distribution, results if, in addition to indistinguishability, it is required that the particles obey the Pauli exclusion principle which permits no more than one electron in each quantum state.

These three distributions may be expressed mathematically as follows where $n(\epsilon)$ gives the number of particles per energy level at energy ϵ when the particles are in thermal equilibrium at temperature T :

$$(1) \quad n(\epsilon) = \frac{1}{e^{(\epsilon - \epsilon_0)/kT}} \quad \text{Maxwell-Boltzmann}$$

$$(2) \quad n(\epsilon) = \frac{1}{e^{(\epsilon - \epsilon_0)/kT} - 1} \quad \text{Bose-Einstein}$$

$$(3) \quad n(\epsilon) = \frac{1}{e^{(\epsilon - \epsilon_0)/kT} + 1} \quad \text{Fermi-Dirac}$$

where k is the Boltzmann constant and ϵ_0 is related to the number of particles present and depends on the temperature in such a way that for energies large compared to kT (so that the probability of occupation for a level becomes considerably less than unity), all three distributions reduce to the Maxwell-Boltzmann distribution.

The appropriate form of statistics to apply to an assembly of particles can also be discussed in terms of the symmetry properties of the wave functions describing the particles. Two classes of wave function ψ (a solution of the SCHRÖDINGER EQUATION for two or more identical particles) result from interchanging all the coordinates, both spatial and spin, in the wave function. It should be noted that this symmetry class does not change as a function of time. The wave functions for particles obeying Fermi-Dirac statistics (fermions) are antisymmetric, while those for bosons (Bose-Einstein statistics) are symmetric. Therefore, for a system of bosons, if all the coordinates of any pair of identical particles are interchanged in the wave function, the new wave function will be identical with the original.

Photons, pi mesons, and all nuclei of even mass number are bosons, while nucleons, electrons, neutrinos, mu mesons and all nuclei of odd mass number are fermions. All known bosons have angular momentum $nh/2\pi$, where n is an integer or zero and h is Planck's constant. The statistics of some nuclei have been determined experimentally by the observation of the relative intensities of

successive lines in the band spectra of homonuclear, diatomic molecules.

One application of Bose-Einstein statistics to a physical situation is the treatment of a "photon gas." It is possible to obtain the Planck distribution law for blackbody radiation by treating the electromagnetic radiation inside an enclosure at constant temperature as a gas of particles of zero rest mass which obey the Bose-Einstein distribution law. This treatment provides an interesting example of the wave-particle duality found in nature, since it is in marked contrast to the original derivation which was based on the wave nature of electromagnetic radiation.

Another interesting application is the explanation of the superfluid properties of liquid helium which occur below the so-called λ point of 2.18°K. Natural helium is composed mostly of He^4 which has zero spin angular momentum and hence is a boson. A qualitative explanation of the superfluid properties of liquid helium is obtained if care is taken not to follow the usual procedure of assuming that the energy states for the bosons are continuously distributed. At low temperatures, the discrete nature of the lowest levels can be important. If one takes account of the fact that an appreciable number of helium atoms will be in the lowest energy state as the temperature is reduced below the λ point, and if one associates these atoms, which have no thermal energy, with the superfluid component, many of the interesting superfluid properties can be understood. It is significant to note that no such properties are observed for He^3 which is a fermion.

BREMSSTRAHLUNG*

An electron can suffer a very large acceleration in passing through the Coulomb field of a nucleus, and in this interaction the radiant energy (photons) lost by the electron is called bremsstrahlung.¹ (bremsstrahlung† sometimes designates the interaction itself). If an electron whose total energy $E_0 \gtrsim 800/Z$ MeV traverses matter of atomic number Z , the electron loses energy chiefly by bremsstrahlung. This case is considered here.

Bremsstrahlung in the coulomb fields of the atomic electrons is adequately included by replacing Z^2 in the formulas by $Z(Z+1)$. For $Z \lesssim 5$, more complicated correction is required.¹

Protons and heavier particles radiate relatively little because of their large masses (radiation rate is proportional to the square of the acceleration,

inversely proportional to the square of the mass). If a very energetic electron traverses one radiation length (λ_0) of any matter, bremsstrahlung reduces the electron's energy to $1/e$ of its incident value on the average. Some examples are:

Element	Air	C	Al	Fe	Cu	W	Pb
Radiation length λ_0 cm	29800	20	9.1	1.7	1.42	0.32	0.51

The energy dependence of radiation loss by an electron of energy E_0 , traversing matter of density n atoms/cc is given by $dE/dx = -nE_0\phi_{\text{rad}}$ where ϕ_{rad} is given by the curves in Fig. 1

FIG. 1. Dependence of the total radiation cross section $\phi_{\text{rad}} \rightarrow (1/E_0) \int_0^{T_0} k d\sigma_k$ on the initial electron kinetic energy, T_0 . The parameter $\phi = Z^2 r_0^2 / 137$.¹

A beam of energetic electrons incident upon a radiator produces a bremsstrahlung beam that is directed sharply forward. Angular distributions for typical "thick" tungsten targets are shown in Fig. 2. Curves for other heavy elements are similar if all radiator thicknesses are measured in units of the radiation length. In such thick radiators, the incident electrons scatter before radiating appreciably, making any observed distribution actually an average over electron scattering angles of the corresponding basic distribution. The basic angular distribution has a zero at $\alpha = 0$, which is quite different from the curves of Fig. 2. The basic spectral shape is a weak function of photon angle and, in thick radiators, electron scattering modifies this shape slightly (Fig. 3). Examples of thick radiator spectra (bremsstrahlung cross sections) are shown in Fig. 4 for various incident electron energies. The bremsstrahlung spectra depend upon screening of the nuclear coulomb field by atomic electrons through the parameter $\gamma = 51k/[E_0(E_0 - k)Z^{1/3}]$, where k is the photon energy in million electron volts. For complete

FIG. 2. Theoretical bremsstrahlung angular distributions from thick tungsten targets for relativistic energies. These data are obtained from the Natl. Bur. Std. *Handbook*, 55. R_α is defined as the fraction of the total incident electron kinetic energy that is radiated per steradian at the angle α .¹

FIG. 3. Dependence of the spectral shape (Schiff's calculation) on the photon emission angle, θ . k is the photon energy in MeV. These curves are from reference 1. T_0 is the incident electron energy in MeV.

screening ($\gamma \approx 0$), the thick radiator spectrum is given by

$$\frac{d\sigma_b}{dk} = \frac{4Z^2r_0^2}{137k} \left\{ \left[1 + \left(\frac{E}{E_0} \right)^2 - \frac{2}{3} \frac{E}{E_0} \right] \cdot \ln(183Z^{-1/3}) + \frac{1}{9} \frac{E}{E_0} \right\} \text{cm}^2/\text{MeV}$$

where E is the final electron *total* energy in million electron volts and r_0 is 2.82×10^{-13} cm. For no screening ($\gamma \gg 1$),

$$\frac{d\sigma_b}{dk} = \frac{4Z^2r_0^2}{137k} \left[1 + \left(\frac{E}{E_0} \right)^2 - \frac{2}{3} \frac{E}{E_0} \right] \cdot \left[\ln \frac{2E_0E}{0.51k} - \frac{1}{2} \right] \text{cm}^2/\text{MeV}$$

Intermediate screening ($2 < \kappa < 15$) leads to much more complicated formulas.¹

FIG. 4. Dependence of the Born-approximation absolute cross section integrated over the photon directions on the photon and electron energy. These curves are from reference 1.

A remark concerning formulas is in order. Generally, expressions for a given cross section are very different depending upon whether the electron energy is small or very large, upon whether the screening is zero, intermediate, or complete, and upon whether one is dealing with the most usual electron-nucleus collisions or with purely electron-electron collisions. Most calculations have been done in Born approximation. The reader is referred to Koch and Motz¹ for an excellent review article on the subject.

The absolute number of bremsstrahlung photons in the photon energy interval dk radiated by a single electron of energy E_0 traversing a radiator of thickness dt and n atoms/cm³ is given by $(d\sigma_b/dk)n dt dk$, where $d\sigma_b/dk$ can be found from Fig. 4.

It must be noted that photon-electron showers begin developing in approximately one radiation length, and these formulas and curves apply only to the basic bremsstrahlung interaction itself or to radiators somewhat thinner than one radiation length.

Bremsstrahlung beams are partially polarized only from extremely thin radiators ($< 10^{-3}$ radiation lengths) because the angular region of

polarization is sharply peaked about the angle $\theta = m_0 c^2 / E_0$. Electron scattering in the radiator broadens the peak and shifts the maximum to larger angles. Polarization is defined by

$$P(\theta, E_0, k) = \frac{d\sigma_+(\theta, E_0, k)}{d\sigma_-(\theta, E_0, k) + d\sigma(\theta, E_0, k)}$$

where an electron of energy E_0 radiates a photon of energy k at angle θ , and \pm directions are with respect to the plane defined by the incident electron and the radiated photon. When the electron is relativistic before and after the radiation, the electric vector is most probably in the \perp direction. Polarization is difficult to observe because thin, low-yield radiators are required. Practical thick-target bremsstrahlung shows no polarization effects whatever. One usually deals with this unpolarized bremsstrahlung and therefore averages over all possible states of polarization of the incident photons. It is clear that if one makes use of polarized photons when investigating electromagnetic interactions, additional information can be obtained.

BROWNIAN MOTION

Brownian motion is the randomly agitated behavior of colloidal particles suspended in a fluid. The phenomenon is named for its discoverer, Robert Brown, an English botanist. In 1828 he observed the "perpetual dance" of microscopic pollen grains suspended in water. Initially, this effect was interpreted as being due to the motions of living matter, but it was later found that *any* tiny particles in suspension exhibit Brownian motion.

In 1888, M. Gouy attributed the motion to the bombardment of the visible particles by invisible thermally excited molecules of the suspension. In 1900, F. M. Exner expressed the view that the kinetic energy of the visible particles must equal that of the surrounding suspension particles, and he attempted to estimate molecular velocities on this basis.

In a series of papers published from 1905 to 1908, Einstein¹ successfully incorporated the

suspended particles into the molecular-kinetic theory of heat. He treated the suspended particles as being in every way identical to the suspending molecules except for the vast difference of their size. He set forth several relationships which were capable of experimental verification and he invited experimentalists to "solve" the problem.

Several workers undertook this task. The most notable of these was Perrin.² Perrin's special success was due to his technique of preparing particles to suspend which were of uniform and known size. The uniformity was achieved by fractional centrifuging, and the size was established by noting that they could be coagulated into "chains" whose length could be measured and whose "links" could be counted. The microscopic observation of these uniform particles enabled Perrin and his students to verify the Einstein results and to make four independent measurements of Avogadro's number. These results not only established our understanding of Brownian motion, but they also silenced the last critics of the atomic view of matter.

Probably the simplest example of Perrin's experiments was his test of the Law of Atmospheres. If we assume that the air is at rest and has the same temperature from ground level upward, it can be shown that the pressure (and concentration) of the air falls off exponentially with increasing altitude. For particles of mass m and density ρ suspended in a medium of density ρ' at absolute temperature T , the ratio of the particle concentrations n_1 to n_2 at heights h_1 and h_2 is given by

$$\frac{n_1}{n_2} = \exp \left[- \frac{mg(\rho - \rho')N_0(h_1 - h_2)}{\rho RT} \right]$$

where N_0 is Avogadro's number, g is the acceleration of gravity, and R is the universal gas constant. Although the concentration of air varies slowly with height, the concentration of the relatively heavy particles varied significantly over a height change of a few millimeters. By observing the concentration variation as a function of height, all quantities in the given equation were known except Avogadro's number which could therefore be determined.

CALORIMETRY

Calorimetry is the science of measuring the quantity of heat absorbed or evolved by matter when it undergoes a change in its chemical or physical state. The apparatus in which the measurement is performed is a calorimeter, and the experimenter is frequently referred to as a calorimetrist.

When matter is involved in a chemical or physical process, its total energy content is usually altered. The difference in energy between its initial and final states, ΔE , must be transferred to, or from, the environment of the system. This energy exchange between the system and its environment is in the form of heat or work or both. In calorimetry, the energy exchanged as heat is quantitatively evaluated. The heat absorbed by the system, q , is related to the work done by the system on its environment, ω , and the increase in internal (total) energy of the system, ΔE , by the thermodynamic relationship

$$q = \Delta E + \omega \quad (1)$$

When calorimetric measurements are performed at constant pressure and only pressure-volume work is involved, q is equal to the increase in heat content or enthalpy, ΔH . Most calorimetric measurements are performed under these conditions, but when other conditions are imposed, appropriate consideration must be made in the thermodynamic treatment of the data.

The process selected for calorimetric study may be a simple change in the physical state of matter, such as a change in temperature of the material, or it may consist of a series of complex chemical reactions such as are encountered in the combustion of many fuels. In fact, nearly any process involving a chemical or physical change in matter might well become a necessary subject for calorimetric investigation.

Calorimetric determinations of energy changes are essential in many theoretical and practical problems. Heat capacity or specific heat data are vital to the design of heat exchange equipment. The thermal properties of steam and certain metals are a major consideration in the design of modern boilers and turbines. The heats of combustion of fuels are essential in rocket, engine and gas turbine design. The heat liberated by chemical reactions must be considered in the development of chemical process equipment. Often the required

equilibrium constant of a process is most conveniently obtained by a simple calculation from the free energy change, ΔF . For a great many processes, numerical values of ΔF can be obtained from the change in heat content, ΔH , and the entropies of the participating substances, S , using the thermodynamic relationship

$$\Delta F = \Delta H - T\Delta S \quad (2)$$

where T is the absolute temperature. The entropies of the individual substances can generally be evaluated from heat capacity measurements that extend to very low temperatures.

The design and constructional details of calorimeters vary widely because of the diversified nature of the processes suitable for calorimetric study. However, the basic principles are general, and their consideration constitutes a common requirement in practically all designs. Suitable devices and procedures for three essential measurements are usually required, but one or two can sometimes be omitted by operating under certain restrictions. The measurements are: (1) the temperature of the calorimeter and its contents, (2) the quantity of energy that is added to the calorimeter from an external source, and (3) the quantity of heat that is exchanged between the calorimeter and its environment.

Most calorimetric operations involve a temperature change, since the heat liberated (or absorbed) during the process is stored in the calorimeter and its contents by virtue of their combined heat capacity. Thermocouples, thermopiles and resistance thermometers are commonly used for temperature measurements. The quantity of energy liberated or absorbed in a calorimetric process is evaluated in terms of electrical energy. This is done by three similar methods. (1) In an exothermic process where heat is liberated, the calorimeter is cooled to the original temperature; the temperature rise is then duplicated using an electrical resistance heater. (2) The heat absorbed in an endothermic process is supplied by an electrical heater at such a rate as to keep the temperature constant. (3) In heat-capacity measurements, the electrical energy is supplied directly by a heater. Electrical energy and temperature can be measured very accurately by modern methods, but the problem of heat transfer between the calorimeter and its environment is more difficult. The minimization of, and accurate

correction for, heat exchange is the major problem to be reckoned with in modern calorimetry.

When two adjacent bodies (such as a calorimeter and its environment) are not at exactly the same temperature, heat is transferred from the warmer to the cooler body. In calorimetry the transfer is made by three major processes: (1) gaseous convection, (2) conduction, and (3) radiation. Gaseous convection can be completely avoided by evacuating the space between the calorimeter vessel and its environment. When evacuation is impractical, convection can be minimized by suitable geometrical considerations in the design of the calorimeter. It is very important to avoid or at least minimize convection, since the heat transported is a complex function of the temperature difference and an accurate evaluation is impossible. Conduction by air or other gases is also usually minimized by evacuating as much as possible of the space between the calorimeter proper and its environment. Conduction in solid materials, used for supporting the calorimeter and for electrical leads, is minimized by proper choice of materials and geometrical design. For small temperature differences, radiation is usually not a serious problem at low temperatures but is a major contributor to heat exchange at elevated temperatures. Heat exchange by radiation can be limited to a few per cent of the blackbody (maximum) values by the use of suitable reflecting surfaces on the outside of the calorimeter and on the adjacent environment. In the absence of convection and for small temperature differences, the heat transferred, Q , is essentially proportional to the temperature difference, ΔT , and time, t , in accordance with Newton's law of cooling.

$$Q = k\Delta Tt \quad (3)$$

It is apparent that anything that can be done in calorimeter design and operation to minimize the terms on the right hand side of Eq. (3) will aid in decreasing the quantity of heat exchanged. Adiabatic calorimeters are operated on the principle that there is no heat exchange and thus no correction to evaluate, if the calorimeter and its environment are maintained at the same temperature.

In calorimeters containing liquids, there is a possibility of a fourth mechanism for transporting heat. This method involves the transport of matter from the calorimeter and its subsequent condensation on the surrounding surfaces. The effect can be avoided by keeping the environment warmer than the liquid or by completely enclosing the liquid. However, even in a completely enclosed system the possibility of vaporization into the space above the liquid with increasing temperature must be considered for volatile liquids.

There are many different varieties of calorimeters, each being particularly suited for a specific type of measurement. Some general features of several representative types are discussed below.

Low-temperature calorimetry has become an important source of heat capacity data for the

evaluation of entropies of substances from measurements extending from near the absolute zero to room temperature or slightly above. The calorimetric vessel consists of a vacuum-tight metal container in good thermal contact with an electrical resistance heater and a thermocouple or resistance thermometer. The sample under study is sealed in the container along with a small amount of gaseous helium. The helium aids in attaining thermal equilibrium at low temperatures because of its high thermal conductivity. The calorimetric vessel is suspended in an evacuated chamber by some material, such as a strong thread, having low thermal conductivity. This chamber is often within a massive copper block which provides a uniform and stable thermal environment. The temperature of the protective block is kept at a temperature near that of the calorimetric vessel. The heat exchanged is evaluated by observing the temperature difference, ΔT , as a function of time and applying Eq. (3) in an integrated form. The constant, k , is evaluated by observing the change in temperature of the calorimeter vessel and its contents under equilibrium conditions. During this rating period, the temperature change is due entirely to heat exchanged with the environment. Some calorimetrists use the adiabatic principle and maintain the temperature of a protective shield as near as possible to that of the calorimeter. This procedure results in the elimination of heat exchange corrections but is not entirely free from objections. Although low-temperature calorimeters are used chiefly for heat capacity determinations, heats of transition, heats of fusion, and heats of vaporization are also measured.

The dropping method is the most common of the accurate high-temperature procedures for measuring heat contents. This apparatus consists of a carefully regulated furnace and a suitable calorimeter, such as a Bunsen ice calorimeter, operating near room temperature. The sample under investigation is sealed inside of a container that will not undergo chemical reaction at the highest temperature of the measurements. The sample and container are thermally equilibrated with the furnace and then dropped into the calorimeter. The empty container is studied in an identical manner and the difference in the two measurements gives the heat content of the sample relative to the room temperature reference. Heat capacities are derived from a series of such measurements as a function of temperature and the thermodynamic relationship:

$$C_p = \frac{\partial(H)}{(\partial T)_p} = \left[\frac{(\partial H}{\partial T} - H_0) \right]_p \quad (4)$$

where C_p is the heat capacity at constant pressure, H the heat content, H_0 the heat content at the reference temperature, and T the absolute temperature.

The Bunsen ice calorimeter is an example of an isothermal calorimeter that is operated at a fixed temperature. The calorimeter is usually surrounded by ice, making it also adiabatic and thus

free from heat exchange. Bunsen's design makes use of the very large difference between the specific volume of ice and water. The calorimeter contains a closed chamber which is full of ice and water. A pool of mercury is maintained in the bottom of the chamber, and as the ice melts, additional mercury enters and keeps the chamber full. The calorimeter has a universal calibration in the form of energy per unit mass of mercury. In early versions, the quantity of ice melted was used as a measure of the heat liberated in the calorimeter. By replacing the ice with other suitable substances, the restriction of operating at one fixed temperature can be removed.

Quantitative measurements of the heat liberated (or absorbed) during the solution of a solid or of another liquid by a solvent are performed in solution calorimeters. Heats of solution, dilution and mixing are common determinations of this type. In addition to participating in the process under investigation, the solvent is used as a means of attaining uniform temperature and composition throughout the calorimeter. This feature necessitates stirring, which is usually accomplished with mechanically or magnetically driven stirrers. Sometimes, however, the calorimeter itself is rotated. Regardless of the method used, the quantity of heat introduced by the stirring must be determined either directly or indirectly and a suitable correction must be applied. Another feature characteristic of solution calorimeters is the method of adding the sample. Either it must be equilibrated with the solvent in the calorimeter, or its heat content relative to the calorimeter temperature must be determined. A common method for solids is immersing a capsule containing the sample in the solvent and breaking it at the desired time.

The heat of combustion of fuels and similar materials is usually measured by bomb calorimetry. The solid or liquid sample is contained in a bomb (pressure vessel) containing excess oxygen or other suitable gas under pressure. The bomb is immersed in a calorimeter containing a liquid, usually water. The reaction is initiated by igniting the sample with a measured amount of electrical energy, and the heat evolved is measured in terms of the temperature rise of the calorimeter. Electrical energy is usually used to duplicate the temperature rise and thus evaluate the heat liberated. However, sometimes a standard sample of a substance having a known heat of combustion such as benzoic acid, is used to calibrate the apparatus. In bomb calorimetry, corrections to standard conditions must be applied (Washburn corrections) since the system is under pressure and because solutions are usually formed.

There are many other important types of calorimeters, such as flow calorimeters, microcalorimeters, flame calorimeters, etc. Nearly any process can be studied by the investigator who is ingenious enough to devise the appropriate apparatus and who has the resources and patience to undertake an extensive project. Although calorimetric measurements are in general time-consuming and tedious, they are essential for a

fundamental and practical understanding of many important chemical and physical processes.

CAPACITANCE

Definition and Fundamental (Quasi) Static Properties. If a constant voltage V [V = volts] is applied between two conductors insulated from each other, electrical charges Q [Q = coulomb] are so distributed that the conductors form equipotentials. The measure for the charges stored is the capacitance C [F = farad = $10^6 \mu F$ = $10^9 m\mu F$ = $10^{12} pF$] of the capacitor so formed.

$$Q[As] = C[F] \cdot V[V] \quad (1)$$

It is often more convenient to express this storing capacity in terms of energy

$$E[Ws] = (1/2)V^2[C[F]] \quad (2)$$

C is defined by

$$C = \frac{1}{V} \int i dt \text{ or } C = I / \frac{dv}{dt} \quad (3)$$

For capacitor discharge (E_0 = starting voltage),

$$e_c/E_0 = e^{-t/\tau} \quad (4a)$$

and for capacitor charge (E_0 = battery voltage)

$$e_c/E_0 = 1 - e^{-t/\tau} \quad (4b)$$

with the time constant τ

$$\tau = CR \quad (5)$$

where R is the resistor through which the capacitor is being (dis)charged.

For sinusoidal excitation of angular frequency ω , the reactance of the lossless capacitor is

$$V[V]/I[A] = (-j)X[\Omega] = 1/j\omega C[\Omega] \quad (6)$$

If, in electrical circuits, capacitors are connected in parallel, their capacitances add

$$C = \sum_{k=1}^n C_k \quad (7a)$$

If capacitors are connected in series, their elastances (the reciprocal of capacitance, S) add

$$S = \sum_{k=1}^n S_k \quad (7b)$$

Losses in the dielectric may be expressed by a complex relative dielectric constant

$$\epsilon = \epsilon' - j\epsilon'' \quad (8)$$

where $\epsilon''/\epsilon' = Q_e$ determines the dielectric quality factor. For $Q_e > 10$, the loss resistance of the capacitor is given by

$$(1/\omega C)/r_n = Q_e = R_p/(1/\omega C) \quad (9)$$

where r_s is the equivalent series and R_p is the corresponding parallel loss resistance. $Q_e = 1/DF$ (DF = dissipation factor). The power factor is related to DF by

$$PF = DF \sqrt{1/(1 + DF^2)} \quad (10)$$

The loss factor $\tan \delta$ (DF) $\cdot \epsilon$ is proportional to the energy loss/cycle voltage²/volume

Capacitors are used for: (1) frequency determining or selective networks [LC circuits and filters; cf. Eq. (6)]; (2) energy storage [Eq. (2)], for instance, the capacitor being slowly charged and quickly discharged [Eqs. (9) and (10)] in a short burst of energy; and (3) integrators and differentiators [in conjunction with R ; cf. Eq. (3)].

Geometry. Uniform Fields. For a uniform field as, for instance, given between two closely spaced parallel metallic plates (area A in square meters, distance l in meters) and disregarding edge effects

$$C[F] = \epsilon_0 \epsilon A/l \quad (11)$$

with ϵ_0 dielectric constant of free space = $(36\pi \times 10^9)^{-1}$ [F/m] and ϵ = the relative dielectric constant (dimensionless) of the material between the plates.

Discontinuity in Uniform Fields. If, in the above case, the dielectric consists of two sheets of different materials with ϵ_1 (having thickness l_1) and ϵ_2 (having thickness l_2)

$$\frac{E_1}{E_2} = \frac{\epsilon_2}{\epsilon_1} \quad (12)$$

where E_n is electric field strength V_n/l_n . (13)

Equation (12) is of great practical significance if one of the ϵ 's is very high, since then the sheet with the low ϵ carries nearly all voltage (for this reason, for example, higher- ϵ ceramic capacitors have to have fired-on electrodes).

Nonuniform Fields. The most common capacitance with nonuniform fields is the coaxial capacitor (inside diameter d , outside diameter D). Its capacitance is

$$C'[\text{pF/m}] = 55.6 \epsilon / \ln(D/d) \quad (14)$$

Extreme cases of nonuniformity, often causing corona, exist on the sharp edges of plate capacitors. Remedy: For field equalization, deform plates to follow equipotential lines of half potential in a capacitive field with twice the spacing of the original, flat plates (Rogowski profile).

Dielectrics. The dielectric "constant" is often not constant but a function of crystal orientation (anisotropy), temperature, voltage, and frequency (dispersion).

The objective of developing a good fixed capacitor is to have the largest capacity in the smallest possible volume for a given operating voltage. Ideally, the capacitance is not to change with voltage, temperature, time, mechanical stress, humidity, and frequency, and (in most cases) is to have a minimum of losses. The greatest capacitance can be achieved by maximizing ϵ (Case a) and A (Case b), and minimizing l (Case c) [cf. Eq. (11)].

Typical for Case (a) are ceramic capacitors made in discoidal or tubular form (and now recently also as coaxially laminated capacitors). There are four classes of ceramic dielectrics:

(1) Semiconducting, so-called layered, ceramics with dielectric constants above 10^3 . These can be used only for very low voltages (transistor circuits), are quite lossy, and have a strong dispersion of ϵ in the megacycle range.

(2) High- ϵ' dielectrics (mostly barium titanates) with ϵ' in the order of 6000. These are quite temperature- and voltage-sensitive (nonlinearity and hysteresis) and are used as guaranteed-minimum-value capacitors (GMV).

(3) So-called stable dielectric capacitors with an ϵ' of 2000 or, if doped with rare-earth materials, with an ϵ' of 3000 to 4000. These are much less dependent on temperature and applied dc voltage.

(4) Linear, high- Q (in the order of several thousand) temperature-compensating capacitors made with a prescribed (P positive, N negative, or NPO) temperature coefficient of the capacity for incorporation in temperature-stable tuned circuits (compensation of the temperature coefficient of the inductance). The ϵ of such materials lies between 10 and 100.

Case (b) (large A) is exemplified best by stacked plates [silvered mica (for military use; excellent Q , temperature coefficient about ± 100 ppm) or ceramic (monolithic)] or rolled dielectric strips [polystyrene (excellent Q ; commercial use; also about ± 100 ppm T.C.); "Mylar"; oil-impregnated paper; "Teflon" etc.].

Case (c) (small l) is represented by polarized capacitors (to make them unpolarized, two capacitors are connected in series in polarity opposition, usually in the same housing), and it includes the older, larger, and cheaper types like the aluminum foil electrolytics. The newer, more costly, but much smaller, types (having much less leakage current) are tantalum oxide capacitors. Ta_2O_5 stands continuously the extraordinary field strength of $3 \cdot 10^6$ V/cm with an ϵ' of 25, l being measured in angstroms. The Q is about 100. For microminiaturization, silicon monoxide or dioxide or tantalum oxide films of very small l are utilized.

Rating. The reliability of a capacitor is predominantly determined by the dielectric and the seal of the housing. One has to distinguish between failure value and withstand value. The failure value of dielectric strength is the voltage at which the material fails and is conventionally given as the average failure voltage. In contrast, the withstand value is a voltage below which no failure can be expected.

Deterioration of capacitors with time (aging) can be greatly reduced by systematic "physics of failure" investigations. Typical failure mechanisms are, for instance, precorona discharge in adsorbed air layers, or silver migration.

Distributed Capacitance. At higher frequencies, the static and quasi-stationary relations listed on p. 89 become useless, and a more rigorous treatment using Maxwell's equations is necessary.

At very high frequencies, capacitors no longer behave like capacitors unless properly modified (see reference 1). Stray capacitances between windings of coils may make the coil resonate and act capacitively beyond the resonance frequency.

Nonlinear Capacitance. The dielectric of highly nonlinear capacitors is the depletion layer formed at the p - n junction by application of proper bias. These back-biased diodes have a reasonable Q and are widely used as nonlinear reactances in parametric amplifiers for VHF and higher frequencies. Nonlinear ceramics are less suitable for this purpose because of their high losses and great temperature dependency.

CARNOT CYCLES AND CARNOT ENGINES

Description. The Carnot cycle is often represented, as shown in Fig. 1, by a device which uses an ideal gas as its working substance. A quantity

of gas is confined in a cylinder with a wall so well insulated that no heat can flow through it. The cylinder's heat-conducting base rests on the first reservoir, whose constant temperature is T_h , and the gas assumes this temperature. A weighted insulating piston holds the pressure of the gas at P_1 at which pressure its volume is V_1 . The gas is then said to be in thermodynamic state 1 characterized by P_1 , V_1 , and T_h . Little by little the weight on the piston is now set aside until the pressure is reduced to P_2 and the volume is expanded to V_2 . The gas is now in state 2 characterized by P_2 , V_2 , and T_h . The transition from one thermodynamic state to another is called a thermodynamic process. This is a reversible process if done so slowly that no temperature differences arise within the gas and if the piston moves without friction. The cylinder base was kept at temperature T_h , so during this process the temperature of the gas remained at T_h ; that is, it was an isothermal process. When this is shown on a pressure-volume diagram, the process appears as a portion of the T_h isotherm. To hold the temperature constant, some heat energy Q_h must flow from the reservoir into the gas. In expanding against the weight on the piston, the gas did work W_{12} which is represented on the P - V diagram by the crosshatched area. The cylinder is next moved to an insulated pad where the pressure is further decreased by setting aside more weights,

FIG. 1. The steps of a Carnot cycle and the corresponding pressure-volume diagrams. The piston location at the start of each process is shown in solid lines; at the end, in dashed lines. The pressure on the gas can be estimated by the area of the weight shown on top of the piston. The dots indicate that the molecules of the ideal gas are close together when the volume is small and are farther apart when the volume is large.

and the gas again expands. No heat energy flows into the gas from the outside during this expansion, and such a process is called an adiabatic process. The temperature decreases and when it reaches T_c , the temperature of the second reservoir, the process is stopped. The gas is now in state 3 characterized by P_3 , V_3 , and T_c . During this process the gas has done work W_{23} against the load. The cylinder is then moved to the second reservoir where enough weights are slowly replaced to bring the gas to state 4, the point on the T_c isotherm from which state 1 can be reached by an adiabatic process. During this isothermal compression, heat energy Q_c flows from the gas into the reservoir, and the piston does work W_{34} on the gas. To show that this work is done on the gas while previously the work was done on the piston, the appropriate portion of the previous crosshatched area has been removed. The cylinder is finally placed on an insulated pad, the remaining weights are slowly added, and the gas returns adiabatically to state 1. Again the fact that the piston does work W_{41} on the gas, is shown by the removal of the cross-hatched area. One Carnot cycle is now completed.

Definition and Characteristics. A Carnot cycle is any reversible cyclic thermodynamic operation composed of four processes which are alternately isothermal and adiabatic. Since no natural process is strictly reversible, the Carnot cycle is an idealization.

The gas is unchanged by the cycle, but heat energy has flowed and work has been done. Heat energy Q_h was removed from the hotter reservoir, and a smaller amount Q_c flowed into the cooler reservoir so that the heat energy budget of the gas increased by $Q_c - Q_h = -Q_{net}$. The net work done by the gas on the piston was $W = (W_{12} + W_{23}) - (W_{34} + W_{41})$. The mechanical energy budget of the gas decreased by W which is represented by the area inside the cycle. The first law of thermodynamics requires that $W - Q = 0$ so there is no energy residue left in the gas. If the cycle is traversed as described, heat energy Q_h is removed from the higher-temperature reservoir. Part of this remains in the form of heat energy Q_c as it flows into the cooler reservoir, and part of it is converted to mechanical energy as the work W done on the piston. A Carnot cycle operated in this direction is called a Carnot engine. If the direction of operation were reversed, the cycle would be called a Carnot refrigerator. In such a device mechanical energy, the work W done by the piston, is converted into heat energy which combines with the heat energy Q_c which flows from the cooler reservoir into the gas. All this heat energy Q_h flows out of the gas into the hotter reservoir.

The efficiency η of any engine is the fraction of the heat energy input Q_h which is converted into mechanical energy W ; that is, $\eta = W/Q_h$. The following properties of Carnot engines are derived in many textbooks of thermodynamics.

- (1) The efficiency of a Carnot cycle depends only on the temperatures of the two reservoirs.
- (2) No heat engine operating in cycles between

two reservoirs can have a greater efficiency than a Carnot engine operating between those reservoirs.

The Carnot engine is thus a standard against which other heat engines can be compared. Historically it was the source of a number of ideas that are now basic to the study of thermodynamics.

History of the Carnot Cycle. In 1824 Sadi Carnot¹ (1796–1832) analyzed a heat engine assuming that heat can perform mechanical work in falling from a higher temperature to a lower just as water can do work in falling from a higher level to a lower, and assuming that since no water is destroyed in the activity, no heat should be lost either. (His work preceded by more than 20 years the theory of Joule and Helmholtz on the mechanical equivalence of heat.) In his study he proposed an ideal heat engine with the following characteristics: it operated in a continuous cycle and it was reversible. He then showed that it is impossible in a cyclic operation to obtain work from a single constant-temperature heat source and that no more work can be obtained from any process than is required to reverse it.

His ideas escaped notice until 1834 when Clapeyron² recognized their merit, suggested some of the details of the device described above, and plotted its behavior on a P - V diagram. Again the ideas were neglected until William Thomson (later Lord Kelvin) learned of Carnot's work through Clapeyron's memoir. In 1848, Thomson described³ how a Carnot engine could be used to define a temperature scale that was absolute in the sense that it did not depend on what thermometric substance was used. It was based on a series of Carnot engines, each of which did the same amount of work. This was the first important idea drawn from a study of the Carnot cycle. In 1850 Clausius⁴, who learned of Carnot's ideas through Thomson and Clapeyron, showed how Carnot's assumption (no loss of heat) could be reconciled with the newer views of Joule and Helmholtz (which now form the basis of the first law of thermodynamics). It was only required that the engine exhaust less heat energy, by the amount of the work done, than it accepted. Thomson independently reached the same conclusion⁵ in 1851.

In 1854 Clausius⁶ in his study of the Carnot cycle identified the physical property he later named "entropy." This was the second important idea drawn from study of the Carnot cycle. In 1877 Boltzmann⁷ took the principle of Clausius that real processes evolve naturally toward states of higher entropy (which is the second law of thermodynamics) as a basic point in his theory and thus had no need to consider the Carnot cycle from which that principle was derived. It is now common practice to discuss thermodynamics axiomatically rather than historically so that the Carnot cycle no longer plays the important role it once did. The most complete discussions are found in the older volumes,⁸ but some recent books do describe the cycle in detail.⁹ An historical account with an elementary presentation of the theory is also available.¹⁰

CAVITATION

Cavities may form, grow, and collapse in a liquid when variational tensile stresses are superimposed on the prevailing ambient pressure. Pure liquids have theoretical tensile strengths which are estimated on various grounds to be of order 300 to 1500 atmospheres (bars), but the observed tensile strengths of real liquids are much lower. It is presumed, therefore, that the observed tensile strength is a measure of the stress required to enlarge the minute cavities, or cavitation nuclei, which already exist in the liquid rather than the stress required to form new interior interfaces.

The transient cavities formed by tensile stress are unstable and would grow indefinitely if the stress were maintained. After the cavitation nuclei have been expanded to many times their original size, however, they may collapse violently if the stress is reduced or removed. The kinetic energy of the liquid that follows each inwardly collapsing interface becomes highly concentrated as the cavity collapses. If such transient cavities contain very little permanent gas, the peak pressures at collapse may reach thousands of bars, the temperature may reach thousands of degrees, and strong SHOCK WAVES may be radiated to a distance of several cavity radii. Similar cavities formed in saturated liquids will usually contain more gas and their collapse will be less violent,

but the peak pressures attained are still sufficient to produce unique mechanical effects such as the corrosion and pitting of metallic surfaces (as in marine propellers and sonar projectors) and the beneficial removal of embedded dirt (as in ultrasonic cleaners). In the latter case, the soil to be removed provides a prolific source of cavitation nuclei at exactly the sites where cavitation is desired.

In hydrodynamic cavitation, the tensile stress is of relatively long duration and plenty of cavitation nuclei are usually available. As a result, cavitation occurs when the total net pressure, or the stagnation pressure, becomes approximately equal to the vapor pressure of the liquid. In acoustic cavitation, the cyclic pressure required to produce cavitation is a function of the frequency, the partial pressure of any dissolved gas, and the population of cavitation nuclei. For frequencies above about 200 kc/sec, the threshold pressure for cavitation increases with the square of the frequency and is almost independent of the degree of gas saturation. For frequencies below 200 kc/sec, the threshold pressure is a function of the partial pressure of the dissolved gas. In saturated liquids, at sound pressures less than a few bars, stable bubbles can grow from cavitation nuclei by the process of rectified diffusion. At higher levels of acoustic excitation, transient cavities can be formed. The threshold sound pressure at which they appear and the violence of their collapse increase as the partial pressure of the dissolved gas is lowered.

The physical nature of the cavitation nucleus, the details of its dynamic growth from sub-microscopic to visible size, and the peak pressures and temperatures achieved at the climax of collapse are current topics of active research interest.

CENTRIFUGE

In most cases, the centrifuge is used for producing sedimentation in fluids, i.e., for the concentration and purification of materials.^{1,2} However, it also has been used extensively as an analytical tool for determining particle or molecular weights and sizes^{1,3,4}; as a means of determining the strength of materials, and numerous other research and practical problems.¹ Centrifugal fields of 10^9 times gravity have been employed in some experiments. The effective centrifugal force, F , on a particle of mass m and density ρ in a fluid of density ρ' is given by the relation $F = m(\rho - \rho')\omega^2 r/\rho$. This force is opposed by the frictional force of the fluid on the particle. If the

speed of sedimentation v is not too large, i.e., the Reynolds number, $v\rho d/\eta$ does not exceed the order of unity, where d is the diameter of the particle and η the coefficient of viscosity, and if the wall effects are neglected, the force of friction f is given by Stokes law. In the case of sedimentation in a liquid for a particle of effective radius a

$$4/3\pi a^3(\rho - \rho')\omega^2 r = 6\pi\eta ar \quad (1)$$

Since ω , r , ρ , ρ' and η are measurable, a and hence the mass of the particle m can be determined. If we are concerned with a substance of molecular weight M , partial specific volume \bar{V} , molar frictional constant f , density of solution ρ , and diffusion constant D , the corresponding equation is³

$$M(1 - \bar{V}\rho)\omega^2 r = f \frac{dr}{dt} \quad (2)$$

For a dilute solution $f = RT/D$ where R is the gas constant and T is the absolute temperature. Hence,

$$v = \frac{dr}{dt} = \frac{MD(1 - \rho\bar{V})}{RT} \omega^2 r \quad (3)$$

The velocity of sedimentation in a unit field $s = \frac{dr/dt}{\omega^2 r}$. If M is known s can be calculated since the other factors in the equation can be determined, or if s is measured, M can be found. The quantity s is called the sedimentation constant and is expressed in Svedberg units (10^{-13} sec)⁻¹ named in honor of the great pioneer in the field of molecular weight measurement by ultracentrifugation. It is a very important quantity for characterizing a substance in solution.^{3,4}

From the above equations alone, one might expect a substance would completely settle out of the solution even with very weak centrifugal fields or gravity alone if the field is applied for sufficient time. This, of course, is not the case because of thermal agitation or BROWNIAN MOTION of the molecules or particles, which gives rise to back diffusion. It can be shown⁵ that the average displacement of a particle in time τ due to Brownian motion is $\Delta X = 2D\tau$ and for a spherical particle of radius a the average velocity for a time τ is

$$v_r = \frac{\Delta X}{\tau} = \left(\frac{RT}{N} \frac{1}{3\pi\eta a\tau} \right)^{1/2}$$

where N is the avogadro number. It is clear that when v_r becomes very much larger than the settling velocity v nothing can sediment out of the solution. When this is the case, it can be shown^{3,4} that when equilibrium is reached between sedimentation and back diffusion

$$\log_e \frac{C_1 f_1}{C_2 f_2} = \frac{M(1 - \rho\bar{V})\omega^2(r_2^2 - r_1^2)}{2RT} \quad (4)$$

where C_1 and f_1 are the concentration and activity coefficient, respectively, at the radius r_1 and C_2 and f_2 are the corresponding quantities at the radius r_2 . If the substance is in dilute solution

in a sector-shaped centrifuge cell, the weight-average molecular weight M_w is given by^{3,4}

$$M_w = \frac{2RT}{(1 - \bar{V}\rho)\omega^2(r_h^2 - r_a^2)} \frac{C_h - C_a}{C_0} \quad (5)$$

where C_a is the concentration at the radius of the meniscus r_a , C_h is the concentration at the peripheral radius r_h and C_0 is the average concentration.

In deriving the above equations, the effect of electrical charges has been neglected. Usually, the solutions are kept near the isoelectric point, but in many important cases this is not possible. The effects of charges on the above equations have been investigated and in some cases found to be quite large.^{3,4,6}

For the separation, purification, or concentration of materials in solution or suspension in a liquid, the centrifugal field is made high enough so that the sedimentation velocity v is appreciable. Equations (1), (2) and (3) are used for estimating the sedimentation. However, these equations hold strictly only when the sedimentation is radial and no turbulence, radial flow, or re-mixing occurs. In most centrifuges used commercially (the cream separator, for example), the liquid flows through the machine during the sedimentation. Any radial flow stream is acted upon by coriolis forces which usually produce mixing. Also, the temperature may not be uniform throughout the sedimenting column. This gives rise to convection if the temperature change produces greater densities near the axis. The driving force which generates thermal convection is roughly proportional to the density gradient times the centrifugal field. Since the latter is large in most centrifuges, the temperature gradient must be small. For a detailed discussion of commercial type centrifuges, both flow-through and batch-type and their operation, reference should be made to Keith and Lavanchy² and others.⁷ In addition to the use of the centrifuge in industry, it is widely used in research and testing laboratories for the purification and preparation of many different substances. As should be expected from theory, high speed centrifuges do not deactivate most molecular species. Even molecular species such as are often encountered in biology and medicine which are stable only over a few degrees of temperature and a small range of pH are not appreciably affected by a comparatively large centrifugal field. For this reason, high speed centrifuges are widely used in biochemistry and molecular biophysics. The rotors of these high speed centrifuges usually spin in a good vacuum (below 10^{-5} torr) to avoid heating and thermal gradients in the rotor. Such centrifuges with push-button control are readily obtainable commercially.

Analytical Centrifuges. The centrifuge is employed as an analytical tool in one of two general methods.^{3,4} The first method makes use of Eqs. (1), (2) and (3), while the second is based upon Eqs. (4) and (5). Sometimes combinations of these two methods are used.^{3,4} When a centrifuge is employed in analytical work, it is usually called

an ultracentrifuge.³ The first method has been more widely used, at least, until recently. In this method, comparatively high rotor speeds with the resulting high centrifugal fields are employed in order to produce an easily measurable rate of sedimentation v . The value of r is usually measured by optical means and s is computed. The high centrifugal field quickly produces a small density gradient across the centrifuge cell which stabilizes the sedimenting column. As a result, very high accuracy in rotor temperature and speed control are not mandatory, although desirable. Another important factor is that the time of centrifugation is comparatively short (~hours). Furthermore, if the solution contains a number of molecular species, each species sediments at its characteristic rate and the value of its sedimentation constant s is easily determined. The effect of ionic charge and the pH of the solution on the values of s and the effect of concentration of one species on the other during sedimentation, etc., have been quantitatively investigated, both theoretically and experimentally, by a number of workers.^{3, 17, 18} The rate-of-sedimentation method has the disadvantage of not being an absolute method and requiring a knowledge of the diffusion constant D as well as the shape of the sedimenting particle or molecule. Often these factors introduce large uncertainties in the value of M .

The second method, known as the equilibrium method, is based upon Eqs. (4) and (5). It is a reliable, absolute method since it is based upon equilibrium thermodynamics. Also, it is not necessary to know the value of the diffusion constant or the shape of the molecule to get the value of M . As pointed out above, no actual sedimentation on the walls of the centrifuge cell occurs in the equilibrium method so that the rotor speed and resulting centrifugal field are relatively low. Consequently, if the concentration of the solute in the solvent is low, the density gradient in the cell is small which in turn makes the sedimenting column sensitive to small rotor temperature and rotor speed variations. Recently, considerable effort has gone into designing and adapting ultracentrifuges to equilibrium measurements and the centrifuging time has been reduced from several days to several hours.^{1, 3, 19} An over-all precision in the measurement of the molecular weights of between 0.1 and 1 per cent over the molecular weight range from 100 to 10⁶ has been obtained.⁹ The determination of molecular weight distributions, etc., can be carried out.

Gas Centrifuging. The centrifuge has been used for removing fine particles suspended in gases and for the separation of gaseous mixtures. The fine particles sediment on the inner wall of the centrifuge where they are removed while the centrifuge is spinning or when it is stopped. In the separation of gases and vapors a tubular type centrifuge is usually used in which the gases flow out of the centrifuge in a light and heavy fraction. Such tubular centrifuges have been used for the separation of isotopes.^{7, 10-12}

When a centrifugal field is applied to a gas it

sets up a pressure gradient

$$dp/dr = Mp\omega^2r = \frac{Mp}{RT}\omega^2r$$

where p is the molar density and P the pressure. In a binary mixture of two ideal gases with molecular weights M_1 and M_2 and with mole fraction N of the lighter gas of molecular weight M_1 , it has been shown both theoretically and experimentally that at equilibrium where r_2 is the radius of the inside periphery of the centrifuge tube

$$\left(\frac{N}{1-N}\right)_{r=r_2} = \left(\frac{N}{1-N}\right)_{r=r_0} \exp \frac{(M_2 - M_1)\omega^2r_2^2}{2RT}$$

In order to determine the value of a centrifuge or cascade of centrifuges for separating isotopes or gases, it is customary to calculate the separative work or separative power which is a measure of separation produced by a single centrifuge or a number of centrifuges used in a cascade. Cohen¹³ has shown that the separative power of a single centrifuge is

$$\delta U = \frac{Dp}{RT} \left[\frac{(M_2 - M_1)\omega^2r_2^2}{2RT} \right]^2 \frac{\pi Z f}{2} \text{ moles/sec}$$

where Z is the centrifuge tube length, D the diffusion constant, and f the flow factor which depends upon the flow pattern in the centrifuge and has a maximum value of one. The number of centrifuges required to carry out a given amount of separation in a time t is $\frac{U}{t\delta U}$ where U is the total separative work and is defined as¹⁴

$$U = W(2N_w - 1) \log_e \frac{N_w}{1 - N_w} + P(2N_p - 1)$$

$$\log_e \frac{N_p}{1 - N_p} + F(2N_F - 1) \log_e \frac{N_F}{1 - N_F}$$

where F is the number of moles of feed material of mole fraction N_F and W and N_w and P and N_p are the corresponding values for the waste and the product. It will be observed that the effectiveness of a centrifuge for gaseous or isotope separation increases directly as the fourth power of the peripheral speed, as the length of the centrifuge, and as $(M_2 - M_1)^2$.

CERENKOV RADIATION

This is a feeble radiation in the visible spectrum, which occurs when a fast charged particle traverses a dielectric medium at a velocity exceeding the velocity of light in the medium. It is thus a shock-wave phenomenon, the optical analog of

FIG. 1

the "supersonic bang." The radiation arises from the local and transient polarization of the medium close to the track of the particle. Consider, Fig. 1(a), an arbitrary element S of the medium to one side of the track AB of a fast electron, the track defining the z -axis. At a particular instant of time, when the electron is at say e_1 , the local polarization vector P will be directed along Se_1' , to a point e_1' slightly behind e_1 , owing to the retarded fields. As the particle goes by, the vector P will turn over and, when the electron reaches e_2 , will be directed to a point e_2' . The variation of P with time, may be resolved into radial and axial components P_ρ and P_z , as shown in Fig. 1(b). Owing to cylindrical symmetry, this polarization, viewed at a point distant from the particle, appears as an elementary dipole lying along the axis z , Fig. 1(c). As the particles plunge through the medium, radiation arises from the coherent growth and decay of this sequence of elementary dipoles. Two essential features of the radiation become at once apparent. First, since it is only the P_z component which is important, the field variation, Fig. 1(b), is that of a double δ -function. Thus, from Fourier analysis, if the circular frequency is ω , we will expect a spectrum of the form $\omega^2 d\omega$, i.e., radiation which is bluer than that from an equi-energy spectrum. Secondly, since the radiating element is an axial dipole, the angular distribution, for this element alone, will be of the form $\sin^2 \theta$, Fig. 1(c). It is important to realize that the radiation arises from the medium itself, not directly from the particle. Since the medium is stationary, the intensity and angular distribution do not contain the relativistic factor (mc^2/E) ;

in this respect, it is essentially different from Bremsstrahlung or synchrotron radiation.

The description above applies only to one element along the track. The most characteristic feature of Čerenkov radiation, its coherence, is at once apparent when we now consider an extended region of track. In Fig. 2(a) it is easily seen that there is only one angle θ at which it is possible to obtain a coherent wave front. If the velocity of the particle is $v = \beta c$, where c is the velocity of light in vacuo, and n is the refractive index of the medium, the particle travels a distance AB in a time Δt , given by $AB = \beta c \cdot \Delta t$; in the same time the radiation, emitted at A ,

travels a distance $AC = (c/n)\Delta t$, from which we obtain the Čerenkov relation:

$$\cos \theta = (1/\beta n) \quad (1)$$

From Eq. (1) it is at once evident that there is a threshold velocity given by $\beta = (1/n)$, below which no radiation takes place. At ultrarelativistic velocities, as $\beta \rightarrow 1$, the Čerenkov angle θ tends to a maximum value $\theta(\max) = \cos^{-1}(1/n)$. The polarization vectors E and H of the radiation which, owing to symmetry takes place over the surface of a cone, are shown in Fig. 2(b).

The radiation yield, from the theory of Frank and Tamm, is

$$\frac{dW}{dz} = \frac{e^2}{c^2} \int_{\beta n > 1} \left[1 - \frac{1}{\beta^2 n^2} \right] \omega \cdot d\omega, \text{ ergs/cm path}$$

or (2a)

$$\frac{dN}{dz} = 2\pi \left(\frac{e^2}{hc} \right) \cdot \left[\frac{1}{\lambda_2} - \frac{1}{\lambda_1} \right] \cdot \sin^2 \theta \text{ photons/cm path}$$

(2b)

between wavelength limits λ_1 and λ_2 (in cm). The spectral distribution is $(dW/d\omega) \propto \omega$ or $(dW/d\lambda) \propto \lambda^{-3}$, expressed as energy per unit circular frequency or per unit wavelength, respectively. The radiation has, therefore, a continuous spectrum toward the blue and ultraviolet. There is no radiation in the x-ray region, for which $n < 1$. For example, in the case of a fast electron in water, $n = 1.33$, we find from Eq. (2b), that when $\beta \rightarrow 1$ and $\theta(\max) = 41^\circ$, the yield (dN/dz) is ~ 200 photons/cm, between λ_1 and λ_2 of 3500 and 5500 Å, respectively.

The phenomenon has found considerable application in the fields of high-energy nuclear physics and cosmic-ray research; in almost all practical Čerenkov counters, the light is detected by means of a photomultiplier. The unique directional and threshold properties of the radiation may be used in a number of different ways. For example, by velocity selection, it is possible to distinguish between particles of different mass having the same energy, and it is also possible to measure particle velocities directly, by measuring θ . Other examples may be cited: The e^2 dependence, Eq. (2) above, has been used to determine the charge spectrum of the primary cosmic rays, and transparent lead-loaded glasses have been developed as total-absorption spectrometers for high-energy γ -rays.

Čerenkov radiation in gaseous media is now used extensively in high-energy physics, light flashes from the night-sky associated with cosmic ray showers have been attributed to the effect, and microwaves have been produced by the Čerenkov process.

CHEMICAL KINETICS

Besides offering useful rate equations to describe the speeds of chemical reactions, chemical kinetics attempts to describe exactly how each reaction occurs. It does so in terms of one or more elementary steps, which are reactions having no observable intermediate chemical species. The ultimate goal is a theory interrelating energy, structure, and time for these single chemical events. Many of the ideas developed since 1850, when the first quantitative rate study was made, have been extended by analogy to explain electron-hole processes in semiconductors, various solid-state processes, and thermonuclear reactions.

Reaction rates depend on the nature of the reactants, temperature, pressure, kind and intensity of radiation, nature of catalyst or solvent, and many other factors. The extent of a reaction can be followed by withdrawal of samples for early chemical analysis. It is more common, however, to analyze the main reaction mixture continuously and nondestructively by spectroscopic means or by observing physical properties like density, electrical conductivity, optical activity, dielectric constant, and so on.

The rate r of a reaction $aA + bB \rightarrow eE + fF$ is best related to the rate of change of the concentrations $[A]$ and $[B]$ of reactants by rewriting the equation as $0 = eE + fF - aA - bB$. If the change is an elementary step, its rate is

$$r = -\frac{1}{a} \frac{d[A]}{dt} = -\frac{1}{b} \frac{d[B]}{dt} = \frac{1}{e} \frac{d[E]}{dt} = \frac{1}{f} \frac{d[F]}{dt} = k[A]^m[B]^n$$

Here k is a rate constant independent of concentration. If the step is not elementary, its rate is often presumed to be expressible as proportional to certain empirically observed powers m, n, \dots of the concentrations of species present in the reaction vessel. The values of m, n, \dots need not be integers and cannot be predicted from the balanced chemical equation if the step is not elementary. The over-all order of a reaction is the sum of these exponents, and the order with respect to a particular species is its own exponent. The order of a reaction can be determined in several ways. In the method of initial rates, concentrations of all but one reactant are held constant, if possible at great values, and v is observed at the start of reaction for several values of $[A]$. The order with respect to A is the slope of a graph of $\log v$ vs. $\log [A]$.

The first major reaction rate theory was founded on the kinetic theory and classical mechanics. It still is very useful when reactants

approach each other in an attractive potential field (e.g., ions), when the distribution of energies is nonequilibrium (e.g., electrical discharge in gases), or when the molecules involved are tremendous in size. In general, however, the collision theory suffers from its inability to satisfactorily predict effective cross sections (molecular sizes for reaction) or the effect of isotopic substitution.

Most modern theories suppose the existence of an undetectable transition state of high energy and fleeting existence. The configuration of this activated complex lies, as it were, atop the mountain pass of lowest height between energy-valleys of reactants and products. It is mechanically stable to all vibrations except the one that describes the progress of reaction over the saddle-point at the pass. This one motion is assigned a very low (sometimes imaginary) frequency, but otherwise the activated complex is just another molecule. It is supposed to be in dynamic equilibrium with reactants and its free energy can be calculated from its partition function by the usual methods of STATISTICAL MECHANICS. The rate constant k , then takes the form $(kT/h) \exp(-\Delta A/kT)$ where k is the gas constant per molecule, T is the absolute temperature, h is Planck's constant, and ΔA is the increase in free energy on going from reactants to activated state. This resembles the well-known relation $k = A \exp(-E/kT)$ discovered empirically in 1889 by Arrhenius. In it, A and E are approximately independent of T , and E is called the activation energy.

A recent theory of promise treats reactants as a wave packet that gradually spreads in time. The rate of reaction is taken to be the probability that the packet will be found in a configuration that is identified with products.

Thermal decomposition of an initially pure gas is seemingly a simple change, yet its order often changes gradually from first to second as the pressure falls. Moreover, there is always the question why like molecules do not all decay at once. The answers lie in understanding the mechanism, which is presently taken to be collision with any other molecule M ($0 \rightarrow A^* + M \rightarrow M + A$ with rate constant k_2') to yield an energized molecule A^* that may suffer a stabilizing collision ($0 \rightarrow A + M \rightarrow M + A^*$, with k_2) or internal change ($0 \rightarrow A^\ddagger \rightarrow A^*$, with k_1) that leads to the activated state A^\ddagger . The reaction is called unimolecular because the activated complex A^\ddagger contains only one reactant molecule. The rate of decomposition of A at any instant is $v = k_2'[M][A] - k_2[M][A^*]$, and the rate of decomposition of A^* is $v^* = k_1[A^*] - k_2'[M][A] + k_2[M][A^*]$. Since the v 's are time derivatives, these are simultaneous differential equations.

It is generally impossible to solve the simultaneous differential equations that describe a mechanism. The least restrictive and most useful simplification is generally the steady-state approximation, wherein the concentration of a species of low concentration is assumed to reach an effectively constant value after a certain

reasonable time (induction period) has passed. If $[A^*]$ reaches a steady-state concentration, $v^* = 0$ and the v^* differential equation becomes an algebraic one for $[A^*]$. Moreover, the rate of decomposition of A then is $v = k_1[A^*] = k_1k_2[M][A](k_1 + k_2[M])^{-1}$. This rate equation becomes second order if $k_2[M] \ll k_1$; this occurs at low pressure or when A^* changes rapidly into A^\ddagger . If A is a simple molecule of few atoms, the activation energy easily becomes effective in one bond to cause decay. On the other hand, the order becomes first if $k_2[M] \gg k_1$; this corresponds to high pressure or an A with many degrees of freedom to accommodate the activation energy.

A generally more restrictive way to simplify the mathematics of a sequence of reactions is to assume that one step is so much slower than the others that it alone limits the rate. All steps besides the rate-limiting one are assumed to be at equilibrium in this approximation. If, in unimolecular decomposition, the rate-limiting step is $A^* \rightarrow A^\ddagger$, then the rate is $k_1[A^*]$. The reaction is then first order in A because $v = 0$ for the equilibrium $A + M \rightleftharpoons M + A^*$. If, however, the rate-limiting step is $A + M \rightarrow A^* + M$, then the rate is $k_2[M][A]$.

Bimolecular reactions, wherein the activated state consists of two reactant species, are very common. The rates of the fastest of these are limited by the rates of diffusion of reactants and have rate constants of the order of 10^{10} liter mole⁻¹sec⁻¹ in aqueous solution. Typical examples are the aqueous neutralizations $NH_4^+ + H_2O \rightarrow NH_3 + H_3O^+$ and $H_3O^+ + F^- \rightarrow HF + H_2O$. Typical bimolecular gaseous reactions are the linear chain reactions $X + H_2 \rightarrow HX + H$ and $H + X_2 \rightarrow HX + X$ where X is H, D, Cl, Br, or I. A nice way to initiate these reactions of H_2 and X_2 is by a photon: $X_2 + \text{photon} \rightarrow X + X$. Thermal dissociation of X_2 is also sufficient to start reaction.

Carbon compounds undergo many reactions, but most of them can be classified into a few types. Nucleophilic substitution, wherein a basic reactant replaces another initially on C by a net reaction $X + RY \rightarrow XR + Y$, may be first order in RY alone or in both X and RY. If first order in just RY, the mechanism is labeled S_N1 and the rate-limiting step is conceived as production of the active carbonium ion R^+ by the process $RY \rightarrow R^+ + Y^-$. If second order (S_N2), the rate-limiting step is considered to be production of the bimolecular activated complex $X \cdots R \cdots Y$. Elimination reactions typically yield a double bond with loss of part of the organic reactant RCH_2CH_2Y . If first order in organic reactant (type E_1), the rate-limiting step is said to be production of the carbonium ion $RCH_2CH_2^+$, which then swiftly eliminates H^- to become $RCH = CH_2$. If first order in both base and organic reactant (type E_2), the rate-limiting step is thought of as production of a bimolecular complex which eliminates H^+ and Y^- almost simultaneously. A fifth class of organic reaction (S_N1) describes how an electrophilic reagent (e.g., NO_2^+ in mixed HNO_3 and H_2SO_4 or Br^+ in

Br_2 with $FeBr_3$) may attack an aromatic ring like that in benzene to form a positively charged intermediate that soon loses H^+ to a base in the solution.

A catalyst is a species that changes the rate of a reaction and yet is regenerated by that reaction so that it seems to be unchanged in the net reaction. Catalysts do not affect the equilibrium state but they do lower the activation energy and sometimes may provide a needed steric arrangement. The most general mechanism of catalysis is $A + C_1 \rightarrow D + C_2$ followed by $B + C_2 \rightarrow E + C_1$ to give the net change $A + B \rightarrow D + E$. Many so-called catalysts of industry need regeneration ($C_2 \rightarrow C_1$) by a reaction other than that catalyzed. For example, silica-alumina cracking catalysts used in making gasoline must be cyclically burned free of carbon deposited during cracking. A catalyzed reaction is almost always first order in catalyst concentration (or surface area) and usually has an order that is less than the true order by unity.

Enzymes are biological catalysts. Many act by the well-known Michaelis-Menten mechanism $E + S \rightleftharpoons C \rightarrow P + E$, where enzyme E attacks substrate S with a rate $k_A[E][S]$ to form a complex C that may yield products P at a rate $k_P[C]$ or may revert to S with rate $k_R[C]$. The rate of disappearance of S is $v_S = k_A[E][S] - k_R[C]$ and the rate of appearance of C or disappearance of E is $v_E = k_A[E][S] - k_R[C] - k_P[C]$. The total concentration of enzyme in the system is $[E]_0 = [C] + [E]$. In the steady state, $v_E = 0 = k_A([E]_0 - [C])[S] - (k_R + k_P)[C]$ so that

$$v_S - k_P[C] = \frac{k_A k_A[S][E]_0}{(k_R + k_P) + k_A[S]}$$

The rate of disappearance of S is always first order in total enzyme but may change from first to zero order in S as $[S]$ increases. The maximum rate at which E can act occurs when $[S]$ is great and $v_S \rightarrow k_P[E]_0$.

CHEMICAL PHYSICS

It is difficult to define each of the traditional fields in science. It is more difficult to define in-between fields. This article will consist mostly of a description of chemical physics that follows brief historical descriptions of chemistry and physics.

During the nineteenth century chemistry dealt with atoms and molecules. It was the science of atoms and their combination. Chemistry was largely empirical and descriptive. Chemists devoted great effort to chemical synthesis and analysis. They made use of precipitation, titration, color changes, weighing, vapor pressure measurements, melting point measurements, and the like. On the other hand, physics dealt with mechanics, electricity and magnetism, wave motion, large-scale properties of matter and so forth. Its tools were those for measuring forces, velocities, electric fields, etc. Physicists had not learned how to treat small-scale mechanics. During this period chemistry and physics seemed to be far apart.

During the early part of the twentieth century physical science leaped ahead. Chemists began to make general use of classical thermodynamics and they became more interested in microscopic phenomena. By 1927 the basic structure of quantum mechanics had been erected and subsequently statistical mechanics was correspondingly modified and expanded.

By 1930 the separation between chemistry and physics no longer existed. The advent of statistical and quantum mechanics and of new, mostly physical, experimental methods and tools wrought great changes in chemistry and physics. The two sciences were able to help each other greatly, and the distinction between them became largely meaningless. It is perhaps unfortunate that chemistry and physics were ever separated. Surely it is true today that chemists need to know much about "physics" and vice versa.

There are many physical problems in which the concepts and methods of the two separate sciences are mixed so that this area may be called chemical physics. A wide range of study is common to both chemistry and physics. The basic problems in chemical physics concern properties of atoms and molecules and the behavior of statistical ensembles of atoms and molecules. Chemical physics is the study of the detailed spatial structures of atoms and molecules, the properties of matter on an atomic and molecular scale, and the application of results to macroscopic properties of matter. Physical chemistry, another interdisciplinary field, is more often concerned with the physical and thermodynamic properties of matter in bulk. Physical chemistry is usually regarded as a branch of chemistry.

We may use *The Journal of Chemical Physics* to explore chemical physics further. The fact that research men chose this journal for publication and that the editors of the journal did publish their papers would seem to indicate that the articles appearing in them "operationally define" chemical physics. Volume 40 of *The Journal of Chemical Physics* was issued during the first half

of 1964. During this interval 529 papers and 189 notes appeared.

The Journal of Chemical Physics lists 35 areas within chemical physics that appeared five times or more. Twelve per cent of these papers were on the kinetics of chemical reactions while 7 per cent dealt with the molecular structure. Within the top 50 per cent there were also, in descending order, papers on crystalline state, thermodynamic properties of matter, liquids, isotope effects, radiation effects, radiation chemistry, and photochemistry. Other topics, in descending order, were solutions, crystal structure, surfaces, energy transfer, polymers, viscosity, diffusion, electrochemistry, free radicals, dielectrics, susceptibility, transport phenomena, valence and chemical bond, rotation within matter, relaxation processes, gases, molecular interactions, phase transitions, conductance, dipole moments, electrical properties, flames, photoconductivity, semiconductors, accommodation coefficients, and photoionization. Each of these topics might well be listed in one or several journals devoted to chemistry, physics, physical chemistry, solid-state physics, etc. It is this combination of topics that is characteristic of the area of chemical physics.

The Journal of Chemical Physics indicates 20 tools or methods that were used by chemical physicists in carrying on their research. Twenty-two per cent used absorption spectroscopy (infrared, visible, and ultraviolet); 18 per cent used magnetic resonance. Within the top 50 per cent, in descending order, were: mass spectroscopy, emission spectroscopy, luminescence, and scattering (molecular, atomic, and x-ray). Also employed were: irradiation, beams (atomic and molecular), x-ray diffraction, conductance, absorption spectroscopy (microwave), Raman spectroscopy, shock waves, nuclear quadrupole resonance, magnetic susceptibility methods, high pressure, light scattering, neutron diffraction, ultrasonics, and electron diffraction. One should note that all of these methods have been developed since 1910. Five have been developed since 1945.

Theoretical methods were identified for 200 papers. They were quantum mechanics (67 per cent), statistical mechanics (26 per cent), thermodynamics (4 per cent), and classical mechanics (3 per cent). Theoretical analyses of microscopic systems and phenomena play a major role in chemical physics. About 40 per cent of the papers were primarily theoretical.

The author knows of eleven graduate schools in the United States that offer majors in chemical physics. It is estimated that the number is in excess of twenty. In many instances these programs are specifically set up for chemical physics students. In other cases the student is simply guided in his selection of chemistry, physics, and mathematics courses.

Other articles in this book discuss in detail some of the major areas in chemical physics.

CHEMISTRY

Chemistry is the branch of natural science that includes knowledge about the nature, composition and transformation of matter and the particular structure of substances and compounds. Because every chemical change always involves one or more physical interactions, chemistry is very closely allied to physics. In fact, current knowledge of atomic structure, both nuclear and extranuclear, was derived almost entirely by using physical concepts and techniques.

Material creativity is dramatically manifested in chemistry, because in this field only is man able to synthesize new combinations of elements, substances and materials. Actually, chemists have created in the laboratory several chemical elements (43, 61, 87, and 93 to 103 inclusive) that apparently are not normally present in or on our planet. Even a cursory examination of the concept of isomerism (the existence of two or more different compounds that have identical compositions) yields the conclusion that literally trillions and trillions of different compounds of carbon could be synthesized by man. In fact, there are possible at least $62 \cdot 10^{12}$ different compounds (called isomers) all having an identical composition indicated by the formula $C_{10}H_{82}$. This specific combination of atoms is just one of millions of other possible combinations, and some of these would have thousands of isomers. The current chemical literature contains documented evidence for either the existence, or the synthesis by man, of well over a million different compounds of carbon. And carbon is only one of the 103 known chemical elements. No wonder, therefore, that chemical nomenclature and notation is of more than a little concern to modern chemists.

Because of the magnitude and latitude of chemistry, several specialized branches have arisen over the years. Some of these divisions are inorganic, organic, analytical, physical, physical organic, chemical physical, quantum chemistry, food chemistry, geochemistry and astrochemistry.

The chemical industry is now a significant part of our economy. The abundance of coal, petroleum and natural gas is one prominent reason for the growth of this branch of commerce. The continually increasing need for commodities such as structural materials, fabrics, fertilizers, pesticides and pharmaceuticals will enhance the chemical industry. The consumption of sulfuric acid, for instance, has for several decades been considered a significant indication of general industrial activity.

Historical Background. The history of alchemy is a fascinating record of man's earliest investigations of matter. However, the alchemist's productivity was seriously hampered by absence of such factors as logical reasoning, unbiased observations and interlaboratory communications. The presence of greed, in some cases, was detrimental.

Robert Boyle and Antoine Lavoisier, two of the earliest proponents of exact quantitative experimentation, exerted profound influences on late

eighteenth and early nineteenth century chemistry. Their techniques were mainly physical.

Around the middle of the nineteenth century, Friedrich Kekulé and Archibald Couper independently proposed a system for writing graphic formulas for chemical compounds. Their concepts were based apparently on the notion that physical forces held together the atoms in compounds. About the same time, general acceptance was finally accorded Amedeo Avogadro's hypothesis (proposed about 50 years earlier) which stated that equal volumes of gases at the same temperature and pressure contain equal numbers of molecules. Acceptance of this physical concept and those of Kekulé and Couper was a marked stimulus to nineteenth century chemical research.

During the period 1860–1900 organic chemistry flourished, and hundreds of compounds were prepared, correctly analyzed and identified, and logically classified as to structure and reactivity. And yet, throughout this period, chemists had no knowledge whatsoever about the structure and composition of atoms. Also they had a rather shallow conception of chemical bonding and molecular geometry. The growth of organic chemistry during the nineteenth century is an epic example of the productivity of sound inductive and deductive reasoning.

Some discoveries in physics that greatly accelerated the growth of chemistry are: Henri Becquerel's discovery of radioactivity (1896) which ultimately led to our current knowledge of atomic nuclear composition and phenomena; the belief in the significance of the electron (Stoney, 1894) which led to the acceptance of the existence of ions; Max Planck's quantum concept (1900); the concepts of probability and the equivalence of mass and energy by Albert Einstein (1905); Niels Bohr's atomic theory (1913); and the duality of the wave and particle character of matter by Louis DeBroglie (1924).

Since 1940 there has been phenomenal growth in the use of spectroscopy in the elucidation of the structure of molecules. The major types of spectra are, in order of seniority, ultraviolet, infrared, nuclear magnetic resonance, and electron spin resonance. Mass spectrometry is valuable in the determination of molecular as well as atomic structure.

During and following World War II there was considerable investigation of the transuranic elements, and of technetium, francium and promethium in relation to their production and use. All these radioactive elements were produced by extraordinary nuclear reactions, whereas all ordinary chemical reactions involve only the electrons outside the nucleus. Ordinary chemical reactions are, in a sense, extranuclear.

The extension, since 1940, of the techniques of column chromatography to other types such as paper, vapor phase (gas), salting-out, and thin-layer has made much easier the separation of the components of complex mixtures. The use of ion-exchange in the resolution of ionic mixtures and in the removal of ions from solutions has been extended during the past twenty years.

The applications of the molecular orbital, crystal-field and ligand-field concepts have been highly successful in the description of the bonding in and geometry of complex molecules. These concepts have firm physical bases.

The decision made by chemists and physicists in 1961 to use a common standard, carbon-12, to assign atomic masses to the chemical elements is a notable landmark in the history of chemistry.

The discovery in 1962 by Neil Bartlett of a stable compound of xenon, $\text{Xe}(\text{PtF}_6)$, was an epic event. Since the discovery of the noble gases during the period, 1894-1900, most chemists had assumed or believed that these elements were either chemically inert or could form only unusual compounds or complexes. Therefore, Bartlett's discovery prompted much activity to produce other noble gas compounds. Several stable binary fluorides, such as XeF_2 , XeF_4 , XeF_6 and KrF_4 are ordinary solid compounds produced by ordinary chemical reactions. Xenon oxy-compounds such as XeO_3 , XeOF_4 and XeOF_6 , although less stable than the binary fluorides, seem to be ordinary compounds.

The importance of chemistry in modern biology, and especially in medicine, has been re-emphasized by knowledge of the role of the nucleic acids, such as DNA and RNA, in the genetic scheme. The increased use of chemotherapy in medicine is common knowledge.

Inorganic Chemistry. This branch of chemistry is mainly that of all forms of noncarbonaceous matter. Although its potential scope is huge, it has attracted, until recently, much less attention than have organic and physical chemistry. The major minerals (except coal, petroleum and lignite) are essentially inorganic. The use of inorganic compounds, especially those of boron and of nitrogen, as fuels and the growth of non-ferrous (other than iron) metallurgy are major developments in inorganic chemistry.

Organic Chemistry. This division of chemistry is essentially that of the compounds of carbon. Originally organic chemistry was confined to materials in or from living organisms, probably because nearly every compound either isolated from or produced by a living organism is a compound of carbon. Although there are more compounds of hydrogen than of any other element, the compounds of carbon are next in line. The property of catenation (ability of identical atoms to bond together) is exhibited most extensively by carbon. The hundreds of different carbon-atom skeletons of the thousands of known organic compounds attest this fact. All foods, nearly every fabric, every ordinary commercial fuel, and almost all pharmaceuticals are organic in the sense they contain compounds of carbon.

Analytical Chemistry. The qualitative and quantitative determination of the elemental composition of matter resides in the branch of chemistry called analytical chemistry. Any means of determining molecular structure is often called an analytical technique. Until relatively recently most analyses were performed by using specific chemical reactions and techniques in liquid

solutions. Recent advances in spectroscopy and other physical techniques have yielded a variety of instruments that greatly facilitate chemical analyses.

Physical Chemistry. The quantitative measurements of the properties and behavior of the elements and their compounds are the major concern of the physical chemist. Nearly every technique and concept has been adopted from physics. The development of new chemical concepts follows logical consideration of quantitative data.

The major branches of physical chemistry are spectroscopy, nuclear chemistry, kinetics, thermodynamics, quantum and statistical mechanics, and solution and surface chemistry. Physical organic and inorganic chemistry have gained prominence during the past 25 years.

Biochemistry. Investigations of the chemical phenomena in, and the constituent compounds of, living organisms are performed mainly by biochemists. Because every chemical reaction in any living organism involves compounds of carbon, biochemistry is essentially the application of organic chemistry to investigations of vital systems. However, both physical and analytical chemistry are essential to biochemistry.

CIRCUITRY

Basic Concepts. As with very many concepts relating to electricity and magnetism, that of the electric circuit very properly may be attributed to James Clerk Maxwell. It was he who took the bold step of ascribing a dual role to the quantity I , which he identified with the current. In perfect conductors, it is the rate of flow of electric charge. In perfect dielectrics, it is proportional to the time rate of change of electric intensity. Above all, however, it has the typical property that it always flows in closed paths. It is this last property upon which the whole concept of electric circuitry is based.

To be more explicit, consider an elementary circuit composed of a resistor R , a capacitor C , and an inductor L , all three connected together end-to-end so that a closed ring or loop is formed. Open this ring at some point and insert a source of electric energy, such as a battery or an alternator that causes an electric current to flow around the closed loop. At any point in the loop the value of the current is equal to its value at any other point. It is this property of the current that determines the configuration of the circuit. The relation of the current to the electromotive force of voltage V generated by the energy source is given by the familiar differential equation

$$V = RI + L \frac{dI}{dt} + \frac{1}{C} \int I dt \quad (1)$$

In a very general sense V may be expressed in the form of the sum of a number of exponentials

$$V = \sum b_m e^{p_m t} \quad (2)$$

where at least one of the b_m 's may be zero. This suggests trying to find solutions of Eq. (1) by expressing the current in the analogous form

$$I = \sum a_m e^{p_m t} \quad (3)$$

When Eqs. (2) and (3) are substituted in Eq. (1) it is seen that the p_m 's must be paired with identical p_m 's. This gives a set of equations each having the form:

$$b_m = R a_m + L p_m a_m + \frac{a_m}{C p_m} \quad (4)$$

There will be one such equation for each value of b_m in Eq. (2). They can be solved to give

$$a_m = \frac{b_m}{R + L p_m + \frac{1}{C p_m}} \quad (5)$$

As remarked above, at least one of the b_m 's may be zero. For this case, the denominator of Eq. (5) must also be zero. Thus, in Eq. (5) there are two values of p_m which apply, namely

$$p_{01} = \frac{R}{2L} \pm j \sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} \approx j\beta \quad (6)$$

$$p_{02} = \frac{R}{2L} \pm j \sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} \approx j\beta \quad (7)$$

When these are reintroduced into Eq. (2), the corresponding values of the a_m 's are determined by the known conditions existing at a given time, for instance at $t = 0$.

From this approach it is easy to generalize. A periodic voltage is the sum of two exponentials $b_1 e^{j\omega t}$ and $b_1 e^{-j\omega t}$. The resulting current is correspondingly the sum of two exponentials

$$\frac{b_1 e^{j\omega t}}{R + j\omega L + \frac{1}{j\omega C}} \quad \text{and} \quad \frac{b_1 e^{-j\omega t}}{R - j\omega L + \frac{1}{j\omega C}}$$

Since the second of these is merely the complex conjugate of the first, both for the voltage and the current, it is convenient for circuit analysis to deal only with the first in both cases. However, the convention breaks down in handling nonlinear systems. There it is necessary to carry the conjugate terms throughout the analysis.

A further step in the generalizing process is to regard Eq. (2) as a Fourier series where the p_m 's are now the imaginaries $\pm j\omega_0$. The quantity $R + j\omega L + 1/j\omega C$ is called the impedance Z . Hence, in a very simple way, for each of the exponentials comprising V , we can express Eq. (1) in the form

$$V = IZ \quad (8)$$

whence

$$I = \frac{V}{Z} \quad (9)$$

The solution of the elementary single-loop circuit is thus reduced to that of a simple algebraic equation.¹

The extension to multi-loop networks follows immediately. It is based on the concept that currents always flow in closed loops and that the values of the loop currents are always the same at any two points in the loop. Figure 1 gives a

FIG. 1

typical configuration.* This shows a three-loop network where the loops are identified by the three currents, I_1 , I_2 and I_3 . In applying Eq. (8) to these three loops, it is necessary to take cognizance of the fact that some of the impedance elements, Z_2 for instance, are subjected to the influence of more than one of the individual loop currents. The current I_1 flows down through Z_2 and the current I_2 flows up through it. The net contribution of Z_2 to the right-hand side of Eq. (8) is $(I_1 - I_2)Z_2$. Thus, the complete description of the network of Fig. 1 is given by the three equations, one for each loop, as follows:

$$\begin{aligned} V_1 &= I_1(Z_1 + Z_2 + Z_3) - I_2 Z_2 - I_3 Z_3 \\ 0 &= -I_1 Z_2 + I_2(Z_2 + Z_4 + Z_6) - I_3 Z_4 \\ 0 &= -I_1 Z_3 - I_2 Z_4 + I_3(Z_3 + Z_4 + Z_5) \end{aligned} \quad (10)$$

Solution yields the currents in the form

$$I_n = \frac{V_{1n}}{Z_{1n}} \quad (11)$$

where Z_{1n} is the transfer impedance from V_1 to the n th current loop. Matrix methods of handling combinations of such networks immediately suggest themselves and these methods have been developed in considerable detail in the literature.^{2,3}

Another generalization involves extending Eq. (2) beyond the Fourier series form to the

* Certain complications occur when circuit networks are of such a topological character that they cannot be represented on a plane surface, as well as when magnetic couplings are involved. However, appropriate extensions of the simple concepts are available for handling these cases.

Fourier integral. Thus, instead of Eq. (2) we have

$$V(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} A(j\omega) e^{j\omega t} d\omega \quad (12)$$

where

$$A(j\omega) = \int_{-\infty}^{\infty} v(t) e^{-j\omega t} dt \quad (13)$$

In this context, Eq. (8) takes the form

$$I(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{A(j\omega)}{Z(j\omega)} e^{j\omega t} d\omega \quad (14)$$

and here all of the matrix generalizations indicated by Eq. (11) may be carried along. In this environment, many of the fundamental properties of the impedance function may be derived.⁴ For example, the fact that a real voltage produces only real currents insures that the real portion of the impedance function is an even function of ω , while the imaginary portion is an odd function. Consideration of the behavior of Eqs. (11), (12) and (13) over the entire complex plane of

$$p = \alpha + j\omega \quad (15)$$

yields further insight into the interesting and useful properties of the impedance function and the entire impedance concept in the environment of Fourier and Laplace transforms.^{4,5}

One of the more important of these expresses the current response of a network to any arbitrary voltage in terms of its response to a vanishingly short pulse of voltage. The response may be measured either in the same loop where the voltage is applied or in a different one. In this aspect, Eq. (11) takes the form

$$I(t) = \int_{-\infty}^{\infty} V(\tau) J(t - \tau) d\tau \quad (16)$$

where $J(t - \tau)$ is the current resulting from a very short pulse of voltage of unit amplitude injected at time $(t = \tau)$. The integral in Eq. (16) is known as the convolution of $V(\tau)$ and $J(t - \tau)$.

Other important properties derivable from consideration of the whole complex plane involve the properties of active vs passive networks, stability requirements for active networks, and requirements for physical realization imposed on the impedance elements and their properties.^{4,6,7}

Nonlinear Circuits. Solution of circuits involving nonlinear relations is in nowhere near as satisfactory a condition. This is not to deny that many of their properties have been discovered and analyzed in rather complete fashion. Those cases where the nonlinearity can be considered as a perturbation on the linear situation have been dealt with satisfactorily. Even in cases involving mixers and modulators, analysis and interpretation is quite straightforward.⁸ However, handling of such situations as the buildup and leveling off of transients in self-oscillatory circuits has made

little progress since the investigations of such pioneers as Balth Van der Pol.⁹

Systems With Time-varying Elements. A number of years ago, interest was aroused in the properties of circuits containing time-varying elements.¹⁰ It was then shown that some of these had amplifying properties. Since no very simple way of producing such elements developed at that time, interest lagged until a few years ago. Now it is realized that modern parametric amplifiers may be handled in this same manner. Moreover, many of the properties of masers and lasers may be interpreted in analogous terms.

Other New Circuit Elements. Of special interest in recent years are circuits that transmit signals differently in different directions. Of course, circuits with vacuum tubes had been known to have this property for many years. Under some conditions, circuits with transistors can be given the same property. These all require sources of power to realize their properties. Some configurations such as those of gyrators, isolators and circulators, possess the property without requiring such sources. True, they do demand the presence of a magnetic field but this need not necessarily require power consumption. The initial application of circuits containing isolators was to prevent changes in the neighborhood of a radio antenna from reacting backwards and affecting the properties of circuitry that was feeding signal energy into the antenna. Later applications allowed multistage parametric amplifiers to be built without encountering backward flow of signal energy in sufficient quantities to produce instabilities in the form of self-oscillations.

Physical Embodiments. While these advances and developments were taking place in the theoretical analysis and technical applications of circuitry, changes of far-reaching significance were in progress in their physical aspects and in materials composing the impedance elements themselves. Originally, resistors, inductors, and capacitors were distinct and separate entities of rather bulky form and unique appearance. Resistors required long lengths of german silver wire, wound so as to reduce the inductive effects, or else lengths of graphite or of volcanic material that went by the name of lavite. Inductors were coils of wire wound on an insulating form either with air core or a core of magnetic material such as soft iron. Capacitors were multi-layer affairs of metallic plates separated by dielectric material which might be either solid or air. Paper was often used for the dielectric.

Nowadays, complicated circuits consisting of many elements in different combinations are formed by various techniques of depositing, spraying or printing materials of many kinds on sheets or cards. Capacitors are formed with much higher capacitance values compressed into volumes much smaller than ever before. Similar advances have been made with inductors. Very thin films of metallic material have contributed to improvements in reliability, stability and accuracy of resistors also.

Switching circuitry has developed very rapidly

† Active networks are those that contain energy sources such as electron tubes or transistors.

in connection with electronic telephone exchanges and digital computers. Circuit elements involve many new devices such as ferreed switches, ferrite memory storage and twistors. Also, it should be noted that optical methods are increasingly being adapted to perform the functions of the older types of circuitry including even such applications as filtering and equalizing. It is probable that the next few years will see remarkable developments and applications along these lines as well as in other directions as yet not even thought of.

CIRCULAR MOTION. See ROTATION—CIRCULAR MOTION.

CLOUD PHYSICS

Gross Dynamics of Clouds. Atmospheric clouds consist of small drops of water condensed from atmospheric water vapor by cooling of the air below its saturation temperature (dew point). Cooling may be induced by radiation near the surface or by temperature contrasts between the air and underlying surface to form clouds near the surface (fog.) Clouds in the upper atmosphere are mostly caused by more-or-less adiabatic cooling due to lifting of the air. Gradual upward vertical motions induced by large-scale atmospheric circulations (~100 km or more in diameter)

usually lead to stratiform clouds, whereas small-scale turbulent motions usually induced by heating from below may result in bunched dense clouds called cumulus (~100 meters to several kilometers in diameter and height).

In meteorological work, a thermodynamic chart with pressure and temperature as the ordinate and abscissa, respectively, is often used to relate the presence of clouds to the vertical temperature and humidity structure of the atmosphere at a given radiosonde station. On such a chart, the adiabatic behavior of an imaginary air parcel may be followed in an imaginary lifting process from any level, particularly the surface, to establish the condensation level (cloud base). The atmosphere's vertical stability may also be evaluated based on whether or not the parcel is negatively (stable) or positively buoyant (unstable) with respect to the atmospheric sounding.

A more realistic representation of convection in the atmosphere may be made by allowing mixing in proper proportions between the parcel and its environment. Observations with a properly instrumented aircraft may eventually be used to relate temperature, liquid water content, drop size and vertical velocity in cumulus clouds by a physically consistent turbulent mixing process between cloud and environment. The relationship of cumulus convection to large-scale atmospheric motions and of the smaller-scale mixing process to the microphysical aspects of cloud drop growth and coalescence are understood only in a rough qualitative sense.

Microphysics of Clouds. Clouds of liquid drops can be formed in a pure atmosphere free of dust or charged particles only by supersaturations of three or four times that over a flat water surface. So many particles are suspended in the earth's atmosphere that maximum initial supersaturations of the order of 1 per cent are all that is required to start the condensation process, which proceeds without appreciable supersaturation once the drops are past a critical size. Computations of the early stages of drop growth indicate that the initial number of drops is established by the initial upward velocity and the number of extremely active condensation nuclei available. Over the oceans the active nucleus spectrum is dominated by sea salt particles of the order of 1μ in diameter (giant salt nuclei).

As a cloud grows, its top may cool below freezing. The cloud drops do not freeze immediately on reaching a temperature of 0°C but tend to supercool to considerably lower temperatures before freezing. Just as condensation is induced with difficulty in pure air, similarly freezing of pure water is also helped by the presence of impurities.

Particles in the air itself may become nuclei for sublimation (condensation from the vapor to the ice phase). Similarly particles in the cloud-drops may induce freezing at certain temperatures of supercooling. The results of laboratory experiments indicate that large water samples or drops tend to freeze at higher supercooling temperatures than small drops. The size dependence of average

freezing temperature has been explained as a sampling effect based on the greater probability of having an active nucleus in a large volume.

Ice-forming nuclei producing ice crystals at temperatures warmer than -20°C have a concentration of the order of one per liter of air. Therefore cloud tops as a rule do not become glaciated until the temperature of -20°C is reached.

The Formation of Rain. A cloud consisting of drops less than 40μ in diameter is quite stable in the sense that they grow only by condensation, not by coalescence. Recent work on the aerodynamics of small droplets indicates that collision of droplets less than 36μ in diameter is impossible. The collision efficiency of clouds consisting of droplets greater than 40μ in diameter rises rapidly as the drop size and drop concentration increase.

The presence of relatively few ice crystals in a supercooled cloud causes it to become unstable regardless of the drop size, since ice crystals at the temperature of supercooled water have a lower vapor pressure. Thus the ice crystals grow at the expense of drops and eventually fall through the cloud growing by coalescence.

Cloud Seeding. Awareness of ice crystals as a source of cloud instability led to cloud seeding experiments. Supercooled stratiform clouds were seeded by dropping dry-ice pellets from an aircraft flying in it. The clouds after seeding were observed to develop holes shaped like the aircraft's path configuration from which light snow showers fell.

Silver iodide in the form of smoke was later introduced as a seeding agent, because its crystal structure was very similar to that of ice. The effectiveness of silver iodide as a sublimation nucleus has been demonstrated in laboratory experiments, but field experiments have not been quite as obviously convincing. Cases of seeding of individual cumulus clouds have resulted in apparent dramatic changes in development, such as explosive vertical growth of firm white cloud tops into fuzzy ice crystal clouds.

Other seeding agents have been tried without convincing demonstrations of their efficacy. For example, clouds above freezing have been seeded with water sprays in attempts to induce a coalescence chain reaction. The injected large drops were expected to grow to a maximum stable diameter of .9 cm and break up into a number of smaller drops, which in turn were expected to grow. The injection of salt particles into clouds to furnish large condensation nuclei in continental clouds has been tried.

Implications for Weather Modification. The possibility of increasing rainfall by cloud seeding was noted in the early stages of experiments on cloud modification. Unfortunately the relation of rainfall observed at the ground to the effect of cloud seeding has proved extremely difficult in the face of the extreme natural variability of precipitation. So far, careful statistical design of weather modification experiments has not produced positive results.

Other forms of weather modification have been

tried or considered. Hail suppression with silver iodide rockets has been attempted without proof of effectiveness. An attempt to weaken a hurricane by seeding with silver iodide smoke bombs has been made with inconclusive results. The use of black topping on the earth's surface is being considered as a means of stimulating cumulus convection by surface heating so as to increase rainfall in favorably situated arid regions. Perhaps a definitive answer to questions on the possibility of weather modification must await a better understanding of the atmosphere.

COHERENCE

Basic Definitions. The term coherence as it is used in electromagnetic radiation studies is best explained by a discussion of Young's interference experiment. Referring to Fig. 1, we consider a self-luminous radiating source S (like a mercury arc lamp) placed a distance l_1 from an opaque screen A . In the screen A two pinhole openings P_1 and P_2 are made a distance d apart. The radiation passing through the pinholes impinges upon and is recorded upon a photographic plate B a distance l_2 from screen A .

If l_1 is a very large distance from A (say $l_1 \gg bd/\lambda$, λ being the average radiation wavelength) and the spectral width of the radiation is made very narrow by filtering, then the fringes observed on B in the neighborhood of O will be very sharp, and we say that the radiation fields impinging upon P_1 and P_2 are very coherent. This is in accord with our usual notions about the radiation from a point source. If, on the other hand, we use the same source and l_1 is taken to be small (say of the order of b) and the dimension b is large compared to d then fringes will not be observed on B , and we say that the radiation fields impinging upon P_1 and P_2 are incoherent. Again this is to be expected since in this case we observe the radiation just as it emerges from the lamp. As the distance l_1 is increased from the order of b , faint fringes will begin to appear upon B . As l_1 increases, the fringes will become progressively stronger until they become very pronounced when $l_1 \gg bd/\lambda$. The intermediate states, when the fringes are present but not necessarily very strong, are termed states of partial coherence. This experiment may be performed using a variety of sources. The experiment, as we have emphasized, measures the coherence of the radiation when it reaches P_1 and P_2 ; it does not measure the coherence of the source.

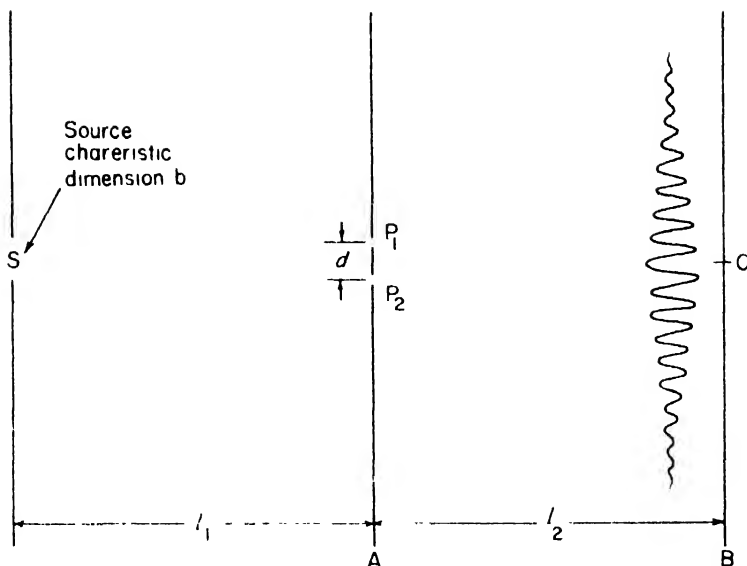

FIG. 1. Young's interference experiment.

A quantitative measure of the fringe strength called the visibility \mathcal{V} , was given by Michelson.¹ It is defined as

$$\mathcal{V} = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \quad (1)$$

where I_{\max} is the maximum intensity recorded in the vicinity of O and I_{\min} is the minimum intensity. \mathcal{V} varies between 0 and 1 and, roughly, we term radiation fields at two points coherent when $\mathcal{V} \approx 1$ (strong fringes) and incoherent (no fringes) when $\mathcal{V} \approx 0$.

In the above introduction, d was held fixed but it is most important to realize that the fringe visibility at O is a function of the spacing d and that \mathcal{V} may be close to 1 for one spacing of d and close to zero for another spacing of d . For example, if we fix l_1 , we will generally decrease the visibility of fringes at O by making d larger (more precisely it will decrease and then increase in a succession of oscillations with the successive peaks being reduced in magnitude.) The visibility may thus be viewed as a measure of the correlation (coherence) between the radiation at P_1 and the radiation at P_2 . To give a more precise definition of coherence, Wolf² considered the correlation function $\Gamma(P_1, P_2, \tau)$, commonly termed the mutual coherence function, defined as

$$\Gamma(P_1, P_2, \tau) = \langle V(P_1, t + \tau) V^*(P_2, t) \rangle \quad (2)$$

where $V(P_1, t)$ is the radiation field at P_1 and time $t + \tau$ (in a scalar approximation), V^* is the radiation field at P_2 at time t and the brackets $\langle \rangle$ denote a time average. For convenience Wolf used a complex notation (V^* is the complex conjugate of V), but this need not concern us here.

It can be shown that the magnitude of the

normalized form of $\Gamma(P_1, P_2, \tau)$, $\gamma(P_1, P_2, \tau)$, where

$$\gamma(P_1, P_2, \tau) = \frac{\Gamma(P_1, P_2, \tau)}{\sqrt{\Gamma(P_1, P_1, 0)\Gamma(P_2, P_2, 0)}} \quad (3)$$

is equal to the visibility \mathcal{V} when the radiation is quasi-monochromatic (narrow spectral width) and all path lengths in the problem are small compared to $c \Delta\nu$ (where c is the velocity of light and $\Delta\nu$ is a characteristic spectral spread). In this case it is appropriate to fix τ at some value τ_0 usually taken to be zero.

The definition given by Eq. (2) was intended to consider polychromatic fields in addition to the quasi-monochromatic fields so often studied using the visibility \mathcal{V} . Beran and Parrent¹ have shown that the full function $\Gamma(P_1, P_2, \tau)$ is, in principle, measurable by an extension of the techniques used in a Young's interference experiment. Modern discussions of coherence now center on the calculation and measurement of the mutual coherence function $\Gamma(P_1, P_2, \tau)$. For calculation it is convenient to note that Wolf² has shown that $\Gamma(P_1, P_2, \tau)$ satisfies the pair of wave equations

$$\nabla_i^2 \Gamma(P_1, P_2, \tau) = \frac{1}{c^2} \frac{\partial^2 \Gamma(P_1, P_2, \tau)}{\partial \tau^2} \quad (i = 1, 2) \quad (4)$$

The vector properties of the electromagnetic field may easily be introduced into the mutual coherence function. In general one must consider the tensor

$$\epsilon_{ij}(P_1, P_2, \tau) = \langle E_i(P_1, t + \tau) E_j^*(P_2, t) \rangle \quad (5)$$

where $E_k(P_k, t)$ is the k th component of the electric field at the space point P_k and time t . In general, this function has proved most useful in the study of polarization effects for fields in

which the radiation has a principal direction of propagation. The form of $\delta_{ij}(P_1, P_2, \tau)$ has, however, been derived for the radiation in a black body cavity.

The above considerations have been for radiation fields that are stationary in time. That is, the statistical parameters, as opposed to the detailed structure of the radiation field, are independent of the absolute scale of time. For fields in which this is not true we must introduce the concept of an ensemble average (similar to that used in statistical mechanics). The mutual coherence function $\delta_{ij}(P_1, P_2, \tau)$ must be replaced by the function $\delta_{ij}^E(P_1, t_1; P_2, t_2)$ defined as

$$\delta_{ij}^E(P_1, t_1; P_2, t_2) = \overline{E_i(P_1, t_1)E_j(P_2, t_2)} \quad (6)$$

where the overbar denotes an average over an ensemble of systems.

Higher-order Coherence Functions and Quantum Aspects. As the concept of coherence grew and the statistical formulation of the theory came more into the fore it was realized that a two-point moment like $\delta_{ij}(P_1, P_2, \tau)$ or $\delta_{ij}^E(P_1, t_1; P_2, t_2)$ was inadequate to completely describe the radiation field. Two fields could have the same mutual coherence function and yet differ in the statistical content of the field. To completely describe the field, it was necessary to consider higher-order moments like $L_{ijkl}(P_1, t_1; P_2, t_2; P_3, t_3; P_4, t_4)$ defined as

$$L_{ijkl}(P_1, t_1; P_2, t_2; P_3, t_3; P_4, t_4) = \overline{E_i(P_1, t_1)E_j(P_2, t_2)E_k(P_3, t_3)E_l(P_4, t_4)} \quad (7)$$

and, in fact, for a complete description it was necessary to consider the probability density functional $P[E_i(P_1, t_1)]$ defined roughly as the probability of the occurrence of a particular realization of the field.

At the writing of this article there is no consensus in the field as to a definition of coherence in terms of all higher moments, and the definition of coherence in terms of second-order moments is still commonly used. There are, however, a number of problems that require consideration of higher-order moments. These moments are necessary in intensity interferometry, the study of laser radiation and the study of the radiation from turbulent gases.

The measurement of the contracted fourth-order moment

$$R_{ik}(P_1, P_2, 0) = \langle [E_i(P_1, t)]^2 [E_k(P_2, t)]^2 \rangle \quad (8)$$

(called intensity interferometry) has received considerable attention since it entailed consideration of the quantum aspects of the electromagnetic field. This moment may be thought of as the correlation of instantaneous intensities

$$I_i(P_1, t) \equiv [E_i(P_1, t)]^2$$

at two points and was originally studied as an alternate method to the measurement of $I'(P_1, P_2, 0)$ for determining the angular diameter of

visible and radio stars.^{4,5} In measuring $I'(P_1, P_2, 0)$, we may use the Young's interference experiment described above; the quantum nature of the field rarely explicitly enters since averaging times are usually long enough to permit a classical analysis. To measure R_{ik} , however, we need to correlate the two signals $I_i(P_1, t)$ and $I_k(P_2, t)$ which are recorded using photomultipliers or coincidence counters. Since the relationship between the impinging electric field and the ejected photoelectron is a statistical one, classical considerations did not suffice for a deep understanding of the problem or for consideration of the very important signal-to-noise problems resulting from inadequate averaging times.

Many studies of the quantum aspects of coherence theory have been made as a result of the intensity interferometry problem, and we refer the reader to Mandel⁶ for a discussion of this subject.

The quantum aspects of coherence theory have also been brought out by the need to consider fourth-order moments when studying laser radiation. The radiation from stars was generally accepted to have gaussian statistics and thus a simple relationship between $I'(P_1, P_2, 0)$ and the scalar analog of $R_{ik}(P_1, P_2, 0)$ is expected. The statistical character of laser light is presently unknown however, and the fourth-order moment is expected to shed new light on the character of laser radiation rather than providing a more convenient measurement as it sometimes did in star measurements. A quantum field formalism for coherence theory intended to consider all types of radiation has been studied by a number of authors (Glauber, Sudarshan, Wolf), and a series of pertinent papers will be found in the proceedings of the Quantum Electronic Conference.⁷

Applications (Measurement of the Angular Diameter of Stars). Coherence theory is of great use in the treatment of imaging and mapping problems. It is especially convenient for treating the problems involving the effects of the atmosphere on resolution. To understand phenomena like the twinkle of stars, it is a natural formalism to introduce. To present the reader with a definite example of the use of the coherence theory formalism, we will conclude this brief discussion with an outline of the measurement of the angular diameter of visible stars.

Let us suppose that the source in Fig. 1 is a visible star so that l_1 is many light-years. There is no telescope big enough to resolve any star, and to make direct measurements of the angular diameter of a star, Michelson introduced the use of interference experiments to essentially give one a bigger effective aperture.

For purposes of visible star measurement we can replace the star of diameter D by a circular disk of diameter D lying in a plane parallel to A . The radiation leaving the star is assumed to be incoherent so that for all points on the disk we may take $I'(P_1, P_2, 0) = c\delta(P_1 - P_2)$. Using Eq. (4) this allows us to solve for $I'(P_1, P_2, 0)$ on the earth (screen A) if we filter the starlight to insure the validity of the quasi-monochromatic

approximation. We find

$$\Gamma(P_1, P_2, 0) = \text{const.} \frac{J_1 \left[\frac{kdD/2}{l_1} \right]}{\frac{kdD/2}{l_1}} \quad (10)$$

where k is the average wave number of the light and J_1 is a first-order Bessel function.

If we define the angular diameter of the star as $\theta = D/l_1$, we see that J_1 equals zero when $\theta = 1.22\lambda/d$, where $\lambda = 2\pi/k$. When J_1 equals zero, there are no fringes on the screen B. Hence to find the angular diameter of the star, we need only increase d from zero, when there will be high contrast fringes, to the separation d when there are no fringes. Putting this latter value into our expression for θ gives us the angular diameter of the star.

COLLISIONS OF PARTICLES

Introduction. Scattering experiments provide the principal technique by which physicists attempt to understand the structure and interactions of matter on a microscopic scale. Scattering theory provides the basis for analyzing and interpreting scattering experiments.

A description of the development of scattering theory may be divided into several topics. The oldest and simplest branch of scattering theory is that of potential scattering, or scattering of two particles which interact through a *local potential*¹. Potential scattering was studied extensively in the first two decades following the development of

quantum mechanics in the analysis of elastic scattering of particles by atoms and of nucleon-nucleon scattering. The latter topic, in particular, led to the introduction of an elaborate theory of scattering by noncentral interactions². The development of nuclear physics, with the observation of resonance reactions, indicated the need for more general descriptions of scattering. The resulting theory of resonance reactions^{3,4} has leaned only rather lightly on the details of the Schrödinger equation. Quantum field theory was developed to describe electromagnetic phenomena. Of major importance in the development of scattering theory was the introduction of renormalization techniques into FIELD THEORY.⁶

It might be claimed that modern scattering theory began with the integral equation formulation of Lippmann and Schwinger and the introduction of S-matrix theory by Heisenberg⁶ and others⁹. This work has stimulated much of the development of theoretical physics in the last decade. Of particular significance are the clarification of the study of rearrangement collisions and the development of the so-called dispersion theoretic techniques.

The Scattering Cross Section. The properties of scattering interactions are usually expressed most conveniently in terms of the *scattering cross section*. To define this term, we consider the following scattering experiment: A beam of particles (called *beam particles*) is directed on a scatterer consisting of *target particles*. As a result of collisions between beam and target particles, there are particles which emerge from the reactions (called *reaction products*) and these are detected in *particle detectors*. To describe this quantitatively, we suppose that the scatterer contains N_t target particles and that this is uniformly illuminated by a flux F_{11} (expressed as the number of beam particles per unit area per unit time arriving at the target) of beam particles. We suppose also that the scatterer is sufficiently small that the beam is negligibly attenuated in passing through it. Then, if there are δN_t scattering interactions per unit time which lead to detected particles, we define the scattering cross section $\delta\sigma$ as:¹⁰

$$\delta\sigma = \frac{\delta N_t}{N_t F_{11}} \quad (1)$$

In the limit that the detectors subtend very small solid angles, as seen from the target, we define the *differential scattering cross section* $d\sigma$. When a single detector, subtending a solid angle $\delta\Omega$, is used to define $\delta\sigma$, we may define the cross section per unit solid angle as

$$\frac{d\sigma}{d\Omega} = \lim_{\delta\Omega \rightarrow 0} \frac{\delta\sigma}{\delta\Omega} \quad (2)$$

The total scattering cross section σ is obtained by summing $\delta\sigma$ over all scattering events:

$$\sigma = \sum \delta\sigma \quad (3)$$

[Equation (3) does not exist for scattering by a coulomb force.]

The scattering cross section may be expressed in terms of the square of the magnitude of a scattering amplitude (or S-matrix, or T-matrix element) and is completely described as a function of the momenta and internal states of the particles in the initial and final states. Thus, for the two particles prior to collision¹¹ we may take the momenta \mathbf{p}_1 and \mathbf{p}_2 and the internal state quantum numbers s_1 and s_2 as variables. (For example, s_1 and s_2 may describe spin orientation, isotopic spin, etc. For colliding molecules these variables will describe vibrational, rotational and electronic states.) We may suppose there to be μ particles in the final state following the collision and specify this state by the momenta and internal variables $\mathbf{k}_1, \dots, \mathbf{k}_\mu, s_1', \dots, s_\mu'$. The scattering cross section may be expressed in terms of these variables. Because of symmetries, the number of variables required to describe $\delta\sigma$ may ordinarily be reduced. The most commonly encountered of these symmetries are: (1) energy and momentum conservation; (2) rotational invariance; (3) the Lorentz invariance of the scattering cross section $\delta\sigma$.¹² The Lorentz invariance of $\delta\sigma$ permits one to describe the scattering in the *barycentric* coordinate system—the coordinate system in which the total momentum of the interacting particles is zero.

This may be illustrated for the special case for which there are only two particles in the initial and two in the final state and an average has been performed over all spin orientations. Then the twelve components of $\mathbf{p}_1, \mathbf{p}_2, \mathbf{k}_1$ and \mathbf{k}_2 may be replaced by only two variables. These may be taken, for example, as the barycentric energy and angle between \mathbf{p}_1 and \mathbf{k}_1 . Convenient variables in relativistic analyses are often chosen to be the Lorentz invariants

$$s \equiv (p_1 + p_2)^2 = (k_1 + k_2)^2$$

$$t \equiv (p_1 - k_1)^2 = (p_2 - k_2)^2 \quad (4)$$

where we have written p_1 , etc., for the four-component energy-momentum vector.

Potential Scattering. We briefly illustrate the discussion of the preceding section with the example of nonrelativistic scattering by a local central potential $V(r)$. The SCHRÖDINGER EQUATION for scattering in the barycentric coordinate system is

$$[\nabla^2 + \kappa^2 - v(r)]\psi_{\mathbf{k}}(\mathbf{r}) = 0 \quad (5)$$

Here $\hbar\kappa$ is the momentum of particle "1" in the barycentric system and $v(r) = \frac{2M_r}{\hbar^2} V(r)$, with M_r the reduced mass of the two particles. In the limit of large separation r between the particles the wavefunction $\psi_{\mathbf{k}}$ has the asymptotic form [our notation is such that we represent a unit vector in the direction of \mathbf{k} by $\hat{\mathbf{k}}$]

$$\psi_{\mathbf{k}}(\mathbf{r}) \rightarrow (2\pi)^{-3/2} \left[e^{i\mathbf{k}\cdot\mathbf{r}} + \frac{e^{i\kappa r}}{r} f(\hat{\mathbf{k}}\cdot\hat{\mathbf{r}}) \right] \quad (6)$$

Here $f(\hat{\mathbf{k}}\cdot\hat{\mathbf{r}})$ is the scattering amplitude for scattering particle "1" from the direction $\hat{\mathbf{k}}$ into the direction $\hat{\mathbf{r}}$. The corresponding cross section per unit solid angle is

$$\frac{d\sigma}{d\Omega} = |f(\hat{\mathbf{k}}\cdot\hat{\mathbf{r}})|^2 \quad (7)$$

The wave function $\psi_{\mathbf{k}}$ may be expanded into partial waves as follows:

$$\psi_{\mathbf{k}}(\mathbf{r}) = \sum_{l=0}^{\infty} \frac{(2l+1)}{4\pi\kappa r} P_l(\hat{\mathbf{k}}\cdot\hat{\mathbf{r}}) i^l e^{i\delta_l} w_l(\kappa; r) \quad (8)$$

Here P_l is the Legendre polynomial of order l , δ_l is the scattering phase shift [see Eq. (10) below], and $w_l(\kappa; r)$ satisfies the differential equation [Eq. (13)]

$$\left[\frac{d^2}{dr^2} + \kappa^2 - \frac{l(l+1)}{r^2} - v(r) \right] w_l = 0 \quad (9)$$

This is to be integrated subject to the condition that w_l is regular at $r = 0$. For large r , w_l has the asymptotic form

$$w_l(\kappa; r) \sim \sqrt{\frac{2}{\pi}} \sin\left(\kappa r - \frac{\pi l}{2} + \delta_l\right) \quad (10)$$

It is Eq. (10) which permits the determination of the phase shift δ_l . The quantity

$$S_l(\kappa) = \exp[2i\delta_l(\kappa)] \quad (11)$$

is an eigenvalue of Heisenberg's S-matrix.⁸

For scattering by noncentral forces, the potential $V(\mathbf{r}, S_1, S_2)$ is a function of \mathbf{r} (and sometimes the orbital angular momentum operator) and the spin operators S_1 and S_2 of the two colliding particles (if either has no spin, we consider its spin operator to be zero). Spin eigenfunctions $u(\nu_1, \nu_2)$ may be introduced as depending on the orientations ν_1 and ν_2 of the respective spins of magnitudes S_1 and S_2 . Then the wave function $\psi_{\mathbf{k}, \nu_1, \nu_2}$ is to be labeled with the initial spin orientations ν_1 and ν_2 . The asymptotic form corresponding to Eq. (6) is

$$\psi_{\mathbf{k}, \nu_1, \nu_2} \rightarrow (2\pi)^{-3/2} \left[e^{i\mathbf{k}\cdot\mathbf{r}} u(\nu_1, \nu_2) + \frac{e^{i\kappa r}}{r} \sum_{\nu_1', \nu_2'} \langle \nu_1', \nu_2' | f(\hat{\mathbf{k}}, \hat{\mathbf{r}}) | \nu_1, \nu_2 \rangle u(\nu_1', \nu_2') \right] \quad (12)$$

Here $\langle \nu_1', \nu_2' | f(\hat{\mathbf{k}}, \hat{\mathbf{r}}) | \nu_1, \nu_2 \rangle$ is the scattering amplitude for scattering to a final spin orientation ν_1', ν_2' . The cross section per unit solid angle is in this case

$$\frac{d\sigma}{d\Omega} = |\langle \nu_1', \nu_2' | f(\hat{\mathbf{k}}, \hat{\mathbf{r}}) | \nu_1, \nu_2 \rangle|^2 \quad (13)$$

For an unpolarized initial state, corresponding to a uniform mixture of the $(2S_1 + 1)(2S_2 + 1)$ spin states, the cross section for scattering particle

"1" into the direction $\hat{\mathbf{r}}$ with any spin orientation is

$$\frac{d\bar{\sigma}}{d\Omega} = \frac{1}{(2S_1 + 1)(2S_2 + 1)} \sum_{\nu_1', \nu_2'} \sum_{\nu_1, \nu_2} |\langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle|^2 \quad (14)$$

where the sums extend over all spin orientations.

Following scattering by noncentral forces, the particles will in general have preferred spin orientations, or be *polarized*. When, for example, particle "1" has spin one-half with a spin operator σ_1 , we define its polarization vector $\mathbf{P}(\nu_1, \nu_2)$ by the equation

$$\mathbf{P}(\nu_1, \nu_2) = \left\{ \sum_{\nu_1'', \nu_2'} [\langle \nu_1'', \nu_2' | f | \nu_1, \nu_2 \rangle]^* \langle \nu_1'' | \sigma_1 | \nu_1' \rangle \langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle \right\} \times \left\{ \sum_{\nu_1', \nu_2'} |\langle \nu_1', \nu_2' | f | \nu_1, \nu_2 \rangle|^2 \right\}^{-1} \quad (15)$$

For an unpolarized initial state, the polarization is

$$\bar{\mathbf{P}} = \frac{1}{(2S_1 + 1)(2S_2 + 1)} \sum_{\nu_1, \nu_2} \mathbf{P}(\nu_1, \nu_2) \quad (16)$$

The study of polarization following scattering has provided an important tool for analyzing nuclear and elementary particle reactions.^{14,15} In particular, the role of noncentral interactions in nucleon-nucleon scattering has been studied in great detail.¹⁶

Formal Scattering Theory. To describe a general scattering reaction Lippmann and Schwinger^{7,17} introduced a scattering matrix \mathcal{T}_{ba} to describe scattering from an initial state χ_a to a final state χ_b .¹⁸ This is defined as

$$\mathcal{T}_{ba} = (X_b, V\psi_a) \quad (17)$$

where ψ_a is the steady-state wave function for the event and V is the scattering interaction. Since momentum is conserved for an isolated scattering, we may write

$$\mathcal{T}_{ba} = \delta(\mathbf{P}_b - \mathbf{P}_a) T_{ba} \quad (18)$$

where \mathbf{P}_a and \mathbf{P}_b are the total momenta of the particles in the initial and final states, respectively, and T_{ba} is defined only for states b and a corresponding to $\mathbf{P}_b = \mathbf{P}_a$.

The scattering cross section $d\sigma$ [Eq. (1)] is expressed in terms of T_{ba} as¹²

$$d\sigma = \frac{(2\pi)^4}{v_{\text{rel}}} \sum_b \delta(\mathbf{P}_b - \mathbf{P}_a) \delta(E_b - E_a) |T_{ba}|^2 \quad (19)$$

Here v_{rel} is the relative velocity of beam and target particles, E_b and E_a are the respective total energies of the particles in states b and a , and the sum on b extends over those states which lead to the reaction products striking the detectors and

thus to register an event. We emphasize that Eq. (19) is Lorentz invariant.¹²

The Heisenberg S-matrix⁸ is given by the expression

$$S_{ba} = \delta_{ba} - 2\pi i \delta(E_b - E_a) \mathcal{T}_{ba} \quad (20)$$

where δ_{ba} is a Dirac δ -function. The S-matrix is unitary, so

$$\sum_c S_{cb}^\dagger S_{ba} = \delta_{ca} \quad (21)$$

On substituting Eq. (20) into this, we obtain the equivalent expression of unitarity

$$i[\mathcal{T}_{ca} - \mathcal{T}_{cb}^\dagger] = 2\pi \sum_b \mathcal{T}_{cb}^\dagger \delta(E_b - E_a) \mathcal{T}_{ba} \quad (22)$$

which is defined only for states c and a on the same *energy shell* (corresponding to $E_c = E_a$).

The fundamental problem of scattering theory is to determine the \mathcal{T} -matrix on the energy shell (or, equivalently, the S-matrix). The first step in doing this is to make use of general symmetry principles (such as Lorentz invariance) to limit the functional forms allowed. Following this a dynamical principle is needed. Such dynamical principles (reviewed in Chapters 5 and 10 of reference¹⁰) have been proposed in a great variety of forms including integral equations, variational principles, and conditions of functional analyticity.

Rearrangement collisions (i.e., collisions in which bound particles rearrange themselves) have been studied extensively following the development of formal scattering theory. Much of this¹⁹ was stimulated by the observance of apparent paradoxes²⁰. An interesting modification of Eq. (17) intended for application to rearrangement collisions has been given by Mittleman.²¹

Another, and not entirely unrelated, class of applications of formal scattering theory concerns scattering by composite systems. These include the multiple scattering and optical model descriptions²² and elaborate theories of atomic scattering processes^{23,24}. The successful development and use of variational principles for such processes should also be noted.²⁵

Field Theory. Quantum field theory was originally developed to describe electro-magnetic phenomena. It was applied in a promising context during the 1930's to β -decay and to the meson theory of nuclear forces. The great optimism following the development of renormalization theory⁶ faded quickly for want of adequate mathematical techniques for handling strong interactions. The most successful applications to strong interactions were the semi-phenomenological calculations of Chew and others^{5,26}.

An interesting and novel attempt to revive field theory has been initiated by Weinberg.²⁷

S-matrix Theory. Heisenberg suggested in 1946⁸ that a proper quantum theory of scattering would deal only with observable quantities such as the S-matrix and should not require off-the-energy-shell matrix elements of such quantities as \mathcal{T} [Eq. (18)]. Considerable impetus for this point

of view has been given by the development of *dispersion theory*, following early suggestions of Wigner and others.²⁸ The first attempt at a systematic formulation of a dispersion relation within the context of quantum field theory was made by Gell-Mann, Goldberger, and Thirring.²⁹ Further development followed applications of formal scattering theory to quantum field theory.³⁰ The development of the Mandelstam representation³¹ provided an important step toward obtaining a "dynamical principle." A further important step was the proposal by Chew and Frautschi and Blankenbecker and Goldberger,³² who suggested that the only singularities of the S-matrix are those required by the unitarity condition [Eq. (22)] and that families of particles should be associated with Regge Trajectories.³⁴

COLOR

Definition. Color is the property of light by which an observer may discriminate between two structure-free patches of light of identical size and shape. If two such patches cannot be distinguished by eye from each other, they are said to match in color.

Conditions for a Color Match. Two patches of light defined physically by their spectral concentrations ($dL/d\lambda$) of radiance L (radiant energy per unit time, unit solid angle, and unit of orthogonally projected area) color match provided that simultaneously:

$$\begin{aligned}\int \bar{x}_\lambda(dL/d\lambda)_1 d\lambda &= \int \bar{x}_\lambda(dL/d\lambda)_2 d\lambda \\ \int \bar{y}_\lambda(dL/d\lambda)_1 d\lambda &= \int \bar{y}_\lambda(dL/d\lambda)_2 d\lambda \\ \int \bar{z}_\lambda(dL/d\lambda)_1 d\lambda &= \int \bar{z}_\lambda(dL/d\lambda)_2 d\lambda\end{aligned}\quad (1)$$

where \bar{x}_λ , \bar{y}_λ , \bar{z}_λ are the color-matching functions of wavelength λ characterizing the observer. Values of these functions customarily used for observers of average normal color vision are those recommended in 1931 by the International Commission of Illumination (CIE); with trivial exceptions any weighted mean of \bar{x}_λ , \bar{y}_λ , \bar{z}_λ , may be substituted for any of them without changing the meaning of Eq. (1). If the two light patches have identical spectral concentrations of radiance, Eq. (1) is satisfied for all observers and describes a nonmetameric match. If Eq. (1) is satisfied even though $(dL/d\lambda)_1$ is different from $(dL/d\lambda)_2$ for some parts of the visible spectrum, Eq. (1) describes a metameric match. Such a color match will usually be a mismatch for observers not characterized by \bar{x}_λ , \bar{y}_λ , \bar{z}_λ .

Deviations from normal color vision are of three types depending on the number of requirements for a color match that have to be satisfied. Anomalous trichromatic vision (protanomalous vision, deuteranomalous vision), like normal trichromatic vision, requires satisfaction of three conditions. Dichromatic vision (protanopia,

deuteranopia, and tritanopia) requires satisfaction of but two conditions, and monochromatic vision (characterizing total color blindness and also characterizing normal vision in sufficiently dim light) requires satisfaction of but one condition. The color-matching function for the usual type of monochromatic vision is the CIE scotopic luminous-efficiency function recommended in 1951. The color-matching functions for the other forms of deviant color vision are related to those (\bar{x}_λ , \bar{y}_λ , \bar{z}_λ) for normal daylight vision as given in Table 1. To make clear this relation, the color-matching functions for normal vision are stated, as is admissible, in terms of $-.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + 0.101\bar{z}_\lambda$ instead of \bar{x}_λ . An alternate statement, to be discussed later, is also given. Figure 1 shows all of these color-matching functions.

Measurement of Color. The integrals of Eq. (1), called tristimulus values, X , Y , Z , serve as specifications of the color of the light patch defined physically by the values of spectral concentration of radiance ($dL/d\lambda$) throughout the visible spectrum. The tristimulus values may be determined visually by having the observer adjust a mixture of three lights, called working primaries, to produce a color match for the specimen light patch. The required amounts of the working primaries, R , G , B , are tristimulus values relative to the working primaries. The tristimulus values, X , Y , Z , relative to the CIE primaries may then be computed from the tristimulus values (X_r , Y_r , Z_r ; X_g , Y_g , Z_g ; X_b , Y_b , Z_b) of the working primaries, thus:

$$\begin{aligned}X &= X_r R + X_g G + X_b B \\ Y &= Y_r R + Y_g G + Y_b B \\ Z &= Z_r R + Z_g G + Z_b B\end{aligned}\quad (2)$$

Photoelectric color measurement may be accomplished by providing a photocell with three filters such that its spectral sensitivity may be made proportional in turn to \bar{x}_λ , \bar{y}_λ , \bar{z}_λ . When the light patch of color to be determined is projected

TABLE 1. COLOR-MATCHING FUNCTIONS FOR VARIOUS TYPES OF TRICHROMATIC AND DICHROMATIC VISION

Type of Vision	Color-matching Function		
	Long-wave Sensitive	Middle-wave Sensitive	Short-wave Sensitive
Trichromatic			
Normal (1, 5, 7)*	$(.639\bar{x}_\lambda + .490\bar{y}_\lambda - .129\bar{z}_\lambda)$	$(-.509\bar{x}_\lambda + 1.410\bar{y}_\lambda + .099\bar{z}_\lambda)$	\bar{z}_λ
(4, 5, 7)*	\bar{y}_λ	$(.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + .101\bar{z}_\lambda)$	\bar{z}_λ
Protanomalous (2, 5, 7)*	$(.32\bar{x}_\lambda + .25\bar{y}_\lambda - .07\bar{z}_\lambda)n^{**}$	$(-.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + .101\bar{z}_\lambda)$	\bar{z}_λ
Deuteranomalous (2, 3-4, 7)*	$(.32\bar{x}_\lambda + .25\bar{y}_\lambda - .07\bar{z}_\lambda)n^{**}$	Intermediate to \bar{y}_λ and $(.312\bar{x}_\lambda + .757\bar{y}_\lambda - .069\bar{z}_\lambda)$	\bar{z}_λ
Dichromatic			
Protanopic (5, 7)*	None	$(-.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + .101\bar{z}_\lambda)$	\bar{z}_λ
Deuteranopic (3-4, 7)*	Intermediate to \bar{y}_λ and $(.312\bar{x}_\lambda + .757\bar{y}_\lambda - .069\bar{z}_\lambda)$	None	\bar{z}_λ
Tritanopic (4, 5)*	\bar{y}_λ	$(-.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + .101\bar{z}_\lambda)$	None

* Numbers of the curves of Fig. 1 showing these color-matching functions.

** The number, n , greater than one, characterizes each individual anomalous trichromatic observer.

Fig. 1. Color-matching functions for normal and various forms of deviant vision:
 Curve 1 = $(.639\bar{x}_\lambda + .490\bar{y}_\lambda - .029\bar{z}_\lambda)$, product of spectral transmittance of eye media by spectral absorptance of photo-pigment presumed to exist in the retina.
 Curve 2 = $(.32\bar{x}_\lambda + .25\bar{y}_\lambda - .07\bar{z}_\lambda)^2$, long-wave-sensitive function for both protanomalous and deuteranomalous vision ($n=2$).
 Curve 3 = $(.312\bar{x}_\lambda + .757\bar{y}_\lambda - .069\bar{z}_\lambda)$, long-wave extreme of the range (shown crosshatched) or deuteranopic long-wave functions; also the long-wave extreme of the deuteranomalous middle-wave functions.
 Curve 4 = \bar{y}_λ , photopic luminous-efficiency function, which is the long-wave-sensitive function for normal and tritanopic vision, and the short-wave extreme of the range (shown crosshatched) of long-wave-sensitive deuteranopic functions and of the middle-wave deuteranomalous functions.
 Curve 5 = $(-.460\bar{x}_\lambda + 1.359\bar{y}_\lambda + .101\bar{z}_\lambda)$, long-wave-sensitive protanopic function, middle-wave-sensitive function for protanomalous and normal color vision, and short-wave-sensitive function for tritanopic vision; also close to $(-.509\bar{x}_\lambda + 1.410\bar{y}_\lambda + .099\bar{z}_\lambda)$, the product of spectral transmittance of eye media by spectral absorptance of photo-pigment presumed to exist in the retina.
 Curve 6 = scotopic luminous-efficiency function, the color-matching function for the usual type of total color blindness.
 Curve 7 = \bar{z}_λ , short-wave-sensitive function for all types of vision except tritanopic and scotopic; also product of the spectral transmittance of the eye media by the spectral absorptance of photo-pigment presumed to exist in the retina.

onto the photosensitive surface with the X -tristimulus filter interposed, the response of the cell will be proportional to $\int (dL/d\lambda)\bar{x}d\lambda = X$; and by inserting the Y -tristimulus filter and the Z -tristimulus filter in turn, Y and Z may be found for the unknown color.

Color Perception and Chromatic Adaptation. The color perception of a spot of light against a dark surround may be described in terms of hue, brightness and saturation. Hue refers to red, orange, yellow, green, blue, purple, back to red, and their intermediates. Brightness determines

whether the patch appears to be emitting more or less light per unit area; it varies from very dim to dazzling. Saturation refers to the amount of difference between the color perception to be described and the neutral color perception (exhibiting no hue) of the same brightness; it varies from neutral to very vivid. Average daylight usually yields a neutral color perception. The color perception of an object illuminated by daylight may be described in terms of hue, saturation (see above) and lightness. Lightness determines whether the object appears to be reflecting a

greater or lesser fraction of the incident light; it varies from a minimum for black to a maximum for white.

The color perception of a spot of light viewed against a dark background correlates well with the tristimulus values of the spot. For example, brightness corresponds to the tristimulus value Y , also known as luminance, but with nonlinear scaling. The cube-root of luminance $Y^{1/3}$ correlates well with estimates of brightness.

The color perception of an object illuminated by average daylight and viewed by a daylight-adapted observer against a white background correlates well with the tristimulus values of the light reflected toward the observer's eye from the object relative to that from the surround. For example, lightness corresponds to Y/Y_s , but with nonlinear scaling where Y_s refers to the surround. The function $(Y/Y_s)^{1/3}$ correlates well with estimates of lightness.

If the light patch or object is viewed by an observer adapted to a color quite different from darkness or daylight (such as by use of a vivid red surround) the color perceptions are markedly changed. If the tristimulus values of the color which appears gray to the observer in his changed state of adaptation be X_a, Y_a, Z_a , and that of the color which appears gray in daylight adaptation be X_1, Y_1, Z_1 , the ratios $X_1/X_a, Y_1/Y_a$, and Z_1/Z_a serve as measures of the changed state of adaptation. The color perceptions then correlate to a first degree of approximation to $(X_1/X_a)X$, $(Y_1/Y_a)Y$, and $(Z_1/Z_a)Z$, instead of to X, Y, Z . Still better approximations are obtained if primaries different from the CIE primaries are used, such as those implied by curves 3, 5, and 7 of Fig. 1. The approximate correlation so achieved is known as the v. Kries coefficient law.

Control of Color by Pigments and Dyes. Objects owe their color to materials (colorants) incorporated in them or spread over their surfaces. Objects viewed by transmitted light usually owe their colors to soluble colorants (dyes). The spectral concentration $dE/d\lambda$, of the radiant flux incident per unit area is changed to $T_\lambda(dE/d\lambda)$ on passage through the dyed object, where T_λ is the spectral transmittance of the object. Objects viewed by reflected light usually owe their colors to insoluble colorants (pigments) which scatter as well as transmit the incident light. The light penetrates the object, and after multiple scattering emerges from the illuminated side. The spectral concentration, $dE/d\lambda$, is changed to $R_\lambda(dE/d\lambda)$, where R_λ is the spectral reflectance of the object.

The colors of objects may be specified by the tristimulus values of the light leaving them toward the observer's eye compared to the tristimulus values of the incident light.

Color Scales. A series of color standards whose colors are suitably spaced over a color range form a color scale. Perhaps the most common example of a one-dimensional color scale is a series of solutions of different colors produced by different concentrations of a known colorant. By visual comparison of a solution of unknown concentration of this colorant with the color standards

making up the scale, the concentration of the unknown may be evaluated. Another one-dimensional color scale is a series of grays ranging from black to white, and still another is the scale of color temperature, defined as the temperature of a blackbody required to make it match the color of an unknown light source to be evaluated.

If the color range is two dimensional, a two-dimensional color scale consisting of a family of one-dimensional scales is required. An example is the range of colors producible by mixing in various proportions paints of any three colors, say black, white, and red. The colors produced by mixing black paint with white paint in various proportions form one of the series of one-dimensional scales, and the other one-dimensional scales might be produced with 10 per cent red paint, 20 per cent, and so on.

If the color range is three dimensional, a three-dimensional color scale is required. The color standards of the Lovibond, the Ostwald, and the Munsell color systems are examples of three-dimensional color scales; the Army solutions form another.

Automatic Production of Pictures in Color. Pictures produced automatically in color as in television, photography, or multiple printing, depend on the principle of photoelectric color measurement. A record of the tristimulus values of each picture element is made either by the television camera or by a camera with photographic film. The final picture is synthesized by the information stored in this record. The synthesis is made by averaging the colors of small spots (television), by addition of colorant layers through which light passes in succession on its way to the observer's eye (most color photography), or by a combination of the two (process printing). The tristimulus values X_a, Y_a, Z_a , of the average color of a group of juxtaposed spots too small to be resolved by eye can be computed simply as the averages of the corresponding tristimulus values of the spots, thus:

$$X_a = (X_1 + X_2 + X_3 + \dots + X_n)/n \quad (3)$$

and similarly for Y_a and Z_a .

The tristimulus value of the light transmitted by three layers of colorants (say magenta, lemon yellow, and cyan) are integrals like those of Eq. (1), where the spectral radiance distribution $dL/d\lambda$ of the source is supplanted by: $T_m T_{ly} T_c(dL/d\lambda)$, where T_m, T_{ly} , and T_c are the spectral transmittances of the magenta, the lemon yellow, and the cyan layers, respectively.

Theories of Color. It is generally supposed that the incidence of radiant energy on an element of the retina is detected by four photopigments present there; one of these (rhodopsin) serves for twilight vision yielding gray perceptions (see curve 6, Fig. 1); the other three (chemical composition unknown) in combination, serve for daylight vision yielding chromatic perceptions (see curves 1, 5, and 7).

Rhodopsin is found in the retinal rods (duplicity theory). The other three photopigments are found in the retinal cones, either segregated full strength (curves 5 and 7), segregated at low concentration

(curve 2), or integrated (either curve 3 or curve 4). Normal vision is explained by triads of receptors (curves 3, 5, 7, or curves 4, 5, 7) according to the three-components or Young-Helmholtz theory.

The signals from the retinal cones are processed on their way to the visual center of the cortex in the occipital lobe of the brain. It is generally supposed that the red, green, and blue signals leaving the retinal cones are converted by this processing into light-dark, yellow-blue, and red-green signals at the occipital lobe. These processes correlate with the following functions of the tristimulus values: *Y* (light-dark), *Y-Z* (yellow-blue), and *X-Y* (red-green). The explanation of normal color vision in terms of these processes is the opponent-colors, or Hering, theory of vision.

Explanations of color vision in terms of a photopigment stage, a receptor stage, and an optic-nerve or cortical stage, are called stage theories of vision (Müller, Adams).

COLOR CENTERS

The term "color center" is broadly used to describe those microscopic defects that produce a change in the optical transparency of materials. The prototypes of these defects are found in the crystals of alkali halides. These crystals consist of positive alkali ions, e.g., K^+ , and negative halide ions, e.g., Cl^- , which are arranged alternately in

a three-dimensional array. If a negative halide ion is removed from its lattice site and put at some other position in the crystal, such as on the surface or into the space between other normal ions, thereby forming an "interstitial ion," a negative ion vacancy results. An electron can be trapped by the positive electric field that arises from the positive ions that surround the negative ion vacancy, thereby forming what may be crudely considered as the analog of the hydrogen atom with the positive field arising from the surrounding alkali ions replacing the positive field of the nucleus. This crystal defect—an electron trapped at a negative ion vacancy—is called an "F-center." The F-center may be in its lowest energy state—the ground state—or it may be excited to higher states by the absorption of a photon of a characteristic frequency. The electron interacts strongly with the positive ions which neighbor the vacancy. Since the position of these positive ions determines the strength of this interaction, any motion of these ions alters the characteristic frequency which is necessary to excite the F-center. There is, therefore, a "band" of frequencies that can be absorbed by a crystal containing F-centers. As the temperature of the lattice is decreased, the motion of the atoms decreases—thereby decreasing the width of the band of frequencies which can be absorbed. Cooling below the temperature of liquid nitrogen ($-196^\circ C$) results in little further change in the width of the band since the vibration of the atoms in the lattice is almost entirely a result of zero-point vibrations below this temperature. As can be seen in Table I, the wavelength (or frequency) of the maximum of the absorption band is characteristic of F-centers in a particular alkali halide crystal.

Following the absorption of a photon, the center is in an excited state. It can return to its ground state by luminescing (i.e., emitting a photon), by ionization of the electron thereby freeing it from the defect, or by a non-radiative process in which the excess energy appears as heat. The relative probability of each of these processes depends upon such parameters as the

temperature, the concentration, and the types of defects. At low temperatures and for low concentrations of defects, the probability that the F-center luminesces approaches unity. As the temperature is raised, the probability for luminescence decreases while the probability for ionization increases. A band of frequencies is emitted when excited F-centers luminesce. The principal frequency of the emitted radiation is always less than the principal frequency of the band of absorbed frequencies. Since the electron distribution in the excited state is different from that in the ground state, the ions in the neighborhood of the F-center shift to a new equilibrium position in the excited state following the absorption of a photon. Energy is therefore given to the lattice with the resulting emitted photon having an energy less than that of the absorbed photon. This is called the Stokes shift of the luminescence.

The ionization of the electron may be detected by observing the current that flows in the presence of an electric field when light is absorbed by the F-center. The disappearance of this photoconductivity at low temperatures is evidence that the first excited state of the center is bound. That is, the electron can be freed from, or ionized out of, the first excited state only if additional energy is provided by the thermal vibrations of the lattice. It is also observed that a strong electric field can provide sufficient energy to "field ionize" the electron out of the first excited state.

The microscopic models of a number of the prominent electron excess centers in the alkali halides are as follows: *F-center*—an electron trapped at a negative ion vacancy. The principal optical absorption band arises from an electronic transition that may be qualitatively classified as $1s \rightarrow 2p$. *M-center*—two F-centers which occupy nearest neighbor positions. The center resembles a hydrogen molecule. The principal optical absorption band corresponds to a ${}^1\Sigma_g \rightarrow {}^1\Sigma_u$ transition. *R-center*—three F-centers that occupy nearest-neighbor positions in a plane. Two distinct absorption bands are associated with this defect. *F'-center*—two electrons trapped at a negative ion vacancy, i.e., an F-center that has trapped an electron.

Alkali halide crystals exhibit strong optical absorptions in the ultraviolet region of the spectrum. The lowest energy of these transitions can be visualized as arising from the transfer of an electron from a negative halide ion to a positive alkali ion thus producing what is called an "exciton." The energy of this transition is perturbed by crystal defects and gives rise to the so-called Greek absorption bands. The α -band arises from an exciton transition in the neighborhood of a negative ion vacancy. The β -band arises from an exciton transition in the neighborhood of an F-center.

In addition to the defects that have trapped an electron, there also exist defects that have a deficiency of electrons—the so-called hole traps. The *V_K-center* consists of a hole that is shared by two negative halide ions. No vacancies are involved in this center. It may be pictured as a Cl_2^-

molecule that occupies two normal halide ion lattice sites in the crystal. The *H-center* consists of a hole that is shared by four negative halide ions that occupy three normal halide ion lattice sites in the crystal. Although this center is also molecular in nature, it may be conveniently pictured as an interstitial halide atom.

Impurities, such as Ti^{2+} , Pb^{2+} , Ag^+ and Cu^+ , introduce one or more absorption bands into the alkali halides when they are substituted for the alkali ion. The nature of these absorption bands depends upon the specific impurity. Impurities can also modify the properties of some of the color centers described above. If a lithium ion replaces a potassium ion that is the nearest neighbor of an F-center in KCl, it is found that two distinct absorption bands appear instead of the single absorption band that arises from the F-center in the pure crystal. This defect—an F-center with a foreign alkali ion impurity as a nearest neighbor—is called the *F_A-center*.

Color centers may be readily generated by the following three techniques:

(1) Irradiation with x-rays, fast electrons, neutrons, or high-energy protons generates color centers which have trapped electrons in equal numbers with those that have trapped holes. The temperature at which the irradiation is made determines the defects that are produced. At room temperature, F-, M- and R-centers are formed. At -196°C , F-, F', V_K - and α -centers are formed. At the temperature of liquid helium (-269°C), F-, H-, V_K - and α -centers are formed.

(2) Heating of a crystal to several hundred degrees centigrade in an atmosphere of the alkali metal produces crystals with a stoichiometric excess of alkali metal. If the crystal is rapidly cooled from this temperature, the F-center is the prominent defect. Absorption of light by the F-centers generates M- and R-centers if the optical irradiation is made at room temperature and F'-centers if the crystal is at about -100°C .

(3) Passage of a dc electrical current through samples held at several hundred degrees centigrade generates color centers. F-centers are generated at the cathode and move into the crystal under the action of the applied electric field.

Many of the properties of the host crystal are strongly affected by the presence of color centers. The density decreases when F-centers are introduced, the thermal conductivity at low temperatures is reduced, the crystal exhibits paramagnetic properties, and an enhanced electrical conduction is observed when the crystal is irradiated with light. Irradiation with x-rays enhances the hardness of the crystal.

Although the microscopic models of the color centers and their interactions with the host lattice and with other defects are best understood in the alkali halides, a considerable amount of information is available on similar defects in other materials. In many cases, the defects have been introduced by irradiation. Studies have been particularly intensive on the alkaline earth halides and oxides, crystalline quartz, fused silica, aluminum oxide, and diamond. Recent studies of

radiation-induced defects in semiconductors, particularly germanium and silicon, have revealed defects that may be properly classified as color centers.

COMPRESSIBILITY, GAS

(a) The *compressibility* of a gas is defined as the rate of volume decrease with increasing pressure, per unit volume of the gas. The compressibility depends not only on the state of the gas, but also on the conditions under which the compression is achieved. Thus, if the temperature is kept constant during compression, the compressibility so defined is called the isothermal compressibility β_T :

$$\beta_T = -\frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T = \frac{1}{\rho} \left(\frac{\partial \rho}{\partial P} \right)_T \quad (1)$$

If the compression is carried out reversibly without heat exchange with the surroundings, the *adiabatic compressibility* at constant entropy, β_S , is obtained:

$$\beta_S = \frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_S = \frac{1}{\rho} \left(\frac{\partial \rho}{\partial P} \right)_S \quad (2)$$

Here P is the pressure, V the volume, ρ the density, T the temperature, and S the entropy.

In adiabatic compression, the temperature rises, thus the pressure increases more sharply than in isothermal compression. Therefore β_S is always smaller than β_T .

The *compressibility factor* of a gas is the ratio PV/RT (cf. GAS LAWS). This name is not well chosen since the value of the compressibility factor by itself does not indicate the compressibility of the gas.

(b) *Experimental values* for the compressibility of gases can be obtained in several ways, most of which are indirect.

Since the compressibility is proportional to the pressure derivative of the volume, any experiment that establishes the P - V - T relation of a gas with sufficient accuracy also yields data for the isothermal compressibility. For obtaining the adiabatic compressibility from the P - V - T relation some additional information is necessary [see section (c)], for instance SPECIFIC HEAT data in the perfect gas state of the substance considered. For recent reviews of experimental methods for determining P - V - T relations of gases, see references 1, 2a and 2b. A more direct way of determining the adiabatic compressibility is by measuring the speed of sound v , the two quantities being related by

$$v^2 = \frac{1}{\rho \beta_S} \quad (3)$$

This relation is valid only when the compressions and expansions of the sound wave are truly reversible and adiabatic. This is the case if the frequency is fairly low and the amplitude small. Experimental techniques for determining the speed of sound are discussed in the literature.^{2a,3}

(c) The experimental behavior of the compressibility as a function of pressure and temperature is as follows: Dilute gases obey the laws of Boyle and Gay-Lussac, $PV = RT$, to a good approximation. Then it is readily shown that the following relations hold for the compressibility:

$$\begin{aligned} \beta_T &= 1/P - V/RT \\ \beta_S &= 1/\gamma P - V/\gamma RT \end{aligned} \quad (4)$$

where $\gamma = c_p/c_v$, the ratio of the specific heats at constant volume and at constant pressure, respectively, and R is the gas constant.

Compressed gases show large deviations from the behavior predicted by Eq. (4). This is demonstrated in Fig. 1, where the isothermal compressibility of argon, divided by the corresponding value for a perfect gas at the same density, is pictured as a function of density for various temperatures. It is seen, first of all, that at all temperatures the compressibility at high densities falls to a small fraction of the value for a perfect gas, and secondly, that super-critical isotherms show a maximum in the ratio $\beta/\beta_{\text{perfect}}$ as a function of density, which maximum is the more pronounced the closer the critical temperature. It occurs roughly at the critical density ρ_c . Since at the critical point $(\partial P/\partial V)_T$ equals zero, the isothermal compressibility becomes infinite at this point. The adiabatic compressibility, however, remains finite. Qualitatively, all gases show the same behavior as pictured for argon in Fig. 1.

(d) The *molecular theory* can explain the general features of the compressibility in its temperature and density dependence. The pressure of the gas is caused by the impact of the molecules on the wall. If the volume is decreased at constant temperature, the average molecular speed and force of impact remain constant, but the number of collisions per unit area increases and thus the

FIG. 1. The ratio $\beta/\beta_{\text{perf.}}$ of the isothermal compressibility of argon to that of a perfect gas at the same density, as a function of the density, at 0.91, 1.02 and 1.08 times the critical temperature. The critical density is indicated by ρ_c .

pressure rises. If the gas is compressed adiabatically, the heat of compression cannot flow off, thus the average molecular speed and force of impact increase as well, giving rise to an extra increase of pressure. Therefore $\beta_s > \beta_T$. The actual magnitude of the temperature rise depends on the internal state of the molecules: the more internal degrees of freedom available, the more energy can be taken up inside the molecule and the smaller the temperature rise on adiabatic compression. Thus for gases consisting of molecules with many internal degrees of freedom, adiabatic and isothermal compressibilities differ but little.

If the gas is assumed to consist of molecules of negligible size and without interaction, then the gas can be shown to follow the laws of Boyle and Gay-Lussac, therefore its isothermal and adiabatic compressibilities must be given by Eq. (4). For a perfect gas, the percentage pressure rise is proportional to the percentage volume decrease if the change is small; thus the compressibility is inversely proportional to the pressure.

To explain the very different behavior of real gases, the model must be modified. Suppose the molecular volume is small but not negligible. In

states of high compression, where the total molecular volume becomes of the order of the volume available to the gas, the free space available to the molecules is only a fraction of what it would be in a perfect gas, and thus the real gas is much harder to compress than the perfect gas. This explains the low compressibility of dense gases and liquids (Fig. 1).

Furthermore, one assumes that molecules, on approaching each other, experience a mutual attraction before they collide; this mutual attraction makes it easier to compress a real gas than a perfect gas. This explains the initial rise of the compressibility of a real gas over that of a perfect gas (Fig. 1) at temperatures not too far above the critical.

When compressed at subcritical temperatures, the gas condenses; that is, macroscopic clusters or droplets are formed under the influence of the attractive forces. During condensation the pressure remains constant while the volume decreases, giving rise to an infinite compressibility in the two-phase region. At the critical point the system is on the verge of condensation and the compressibility is also infinite.

(e) *Theoretical predictions* for the isothermal compressibility can obviously be obtained from any theory of the equation of state (cf. GAS LAWS). If, in addition, data for the specific heat are supplied, the adiabatic compressibility can be derived in the same way. Thus the compressibility can be derived from the virial expansion of the equation of state which expresses the ratio PV/RT in a power series in the density, the coefficients being related to the interactions of groups of two, three, etc., particles.^{4,5}

In the dense system the convergence of the virial expansion is doubtful. In any case the higher coefficients are hard to calculate; here approximate theories have been developed, of which the cell model⁵ is an example.

Many semiempirical equations of state with varying degree of theoretical foundations are in use. The van der Waals equation, a two-parameter equation which gives a qualitatively correct picture of the P - V - T relations of a gas and of the gas-liquid transition, is an example. For a survey of the most useful semiempirical equations of state, see reference 5.

Modern developments are centered around the calculation of the radial distribution function $g(r)$, which is the ratio of the density of molecules at a distance r from a given molecule, to the average density in the gas. The compressibility can be expressed straightforwardly in terms of $g(r)$ as follows:⁵

$$KT\beta_T = 1/\rho + \int_0^\infty [g(r) - 1]4\pi r^2 dr \quad (5)$$

Approximate evaluations of the radial distribution function in dense systems are being obtained as solutions to integral equations derived from first principles under well-defined approximations. For a survey of the approaches used, see reference 6.

COMPTON EFFECT

Introduction. The Compton effect refers to the collision of a photon and a free electron in which the electron recoils and a photon of longer wavelength is emitted as indicated in Fig. 1. It is one of the most important processes by which x-rays and γ -rays interact with matter and is also one which is accurately calculable theoretically.

A discussion of the effect is found in most textbooks on atomic physics. Particularly complete presentations have been made by Evans.^{1,2}

History. Barkla and others (1908) made many observations on the scattering of x-rays by different materials. The diffuse scattering was interpreted qualitatively by J. J. Thomson in terms of the interaction of electromagnetic waves with electrons which he had shown to be a constituent of all atoms. As more experiments were carried out with light elements, it was established by J. A. Gray (1920) that the diffusely scattered x-rays were less penetrating. This implied that the scattered radiation had a longer wavelength than the incident radiation. This could not be reconciled with Thomson's theory which represented x-rays as continuous electromagnetic waves with wavelengths unchanged by scattering.

The effect which now bears his name was established quantitatively by Arthur Holly Compton (1923) when he published careful spectroscopic measurements of x-rays scattered at various angles by light elements. He found that x-rays scattered at larger angles had systematically larger wavelengths. In searching for an explanation of the data, he discovered that the observations were accounted for by considering the

scattering as a collision between a single photon and a single electron in which energy and momentum are conserved.

The important place which the effect occupies in the development of physics lies in his interpretation of the effect in terms of the newly emerging quantum theory. The essential duality of waves and particles was demonstrated in an especially clear way, since the collision conserved energy and momentum while both the incident and scattered x-rays revealed wave-like properties by their scattering from a crystal. In recognition for this contribution, Compton was awarded the Nobel Prize in 1927.

A complete theory for the effect was worked out in 1928 by Klein and Nishina using Dirac's relativistic theory of the electron. The calculation was one of the brilliant successes of the Dirac theory. It represents quantitatively, within the experimental uncertainties, all phenomena associated with the scattering of photons by electrons for energies up to several billion electron volts. Because of the confidence with which photon interaction with electrons can be interpreted, the Compton effect has been important in the analysis of the energy and the polarization of gamma rays from many sources.

FIG. 1. Diagram showing the initial and final energies and momenta for Compton scattering.

Kinematics. The relations between the energies and directions of the incident and scattered photons and the recoil electron are determined by the conservation of energy and of the components of momentum parallel and at right angles to the incident beam. In the usual case, where the electron is initially at rest and the energy and momentum of the incident photon are $h\nu$ and $(h\nu/c)$, the equations are:

$$h\nu = h\nu' + T \quad (1)$$

$$\frac{h\nu}{c} = \frac{h\nu'}{c} \cos \theta + p \cos \phi \quad (2)$$

$$0 = \frac{h\nu'}{c} \sin \theta - p \sin \phi \quad (3)$$

where c is the velocity of light, h is Planck's constant, and the angles are those indicated in Fig. 1. The relativistic relation between the kinetic energy T of the recoiling electron and its momentum p is

$$pc = \sqrt{T(T + 2mc^2)} \quad (4)$$

where m is the mass of the electron. These equations can be combined to obtain relations which are useful in the interpretation of data. The Compton shift is

$$\lambda' - \lambda = \frac{c}{\nu'} - \frac{c}{\nu} = \frac{h}{mc} (1 - \cos \theta) \quad (5)$$

This relation was first found experimentally by Compton, who noted that the shift in wavelength ($\lambda' - \lambda$) depended on the angle, but not on the wavelength, of the incident photon. The quantity (h/mc), which is the shift at 90° , is called the Compton wavelength of the electron and is one of the useful constants (2.4262×10^{-10} cm).

$$h\nu' = \frac{mc^2}{1 - \cos \theta + \frac{mc^2}{h\nu}} \quad (6)$$

In this form, the energy of the scattered photon is seen to vary from that of the incident photon at 0° to less than $(mc^2/2)$ at 180° . At high energies the angle θ for which $h\nu'$ is $(h\nu/2)$ is approximately $2(mc^2/h\nu)$ radians.

The kinetic energy of the recoiling electron is

$$T = \frac{h\nu(1 - \cos \theta)}{(1 - \cos \theta) + \frac{mc^2}{h\nu}} \quad (7)$$

The relation between the scattering angles of the electron and photon is

$$\cot \phi = \left(1 + \frac{h\nu}{mc^2}\right) \left(\frac{1 - \cos \theta}{\sin \theta}\right) \quad (8)$$

Graphs of these kinematic relations and of the scattering cross section are given by Evans⁽²⁾ and by Nelms⁽³⁾.

Scattering of Unpolarized Radiation. The differential cross section for the scattering of unpolarized radiation at an angle θ is given by the Klein and Nishina equation.

$$\frac{d\sigma}{d\Omega} = \frac{r_0^2}{2} \left(\frac{\nu'}{\nu}\right)^2 \left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - \sin^2 \theta\right) \quad (9)$$

where r_0 is the electron radius $= e^2/mc^2 = 2.8177 \times 10^{-13}$ cm, and ν' is obtained from Eq. (6). The cross section is shown as a function of θ for several energies in Fig. 2. The classical Thomson cross section $r_0^2 (1 + \cos^2 \theta)/2$ can be seen to hold for low energies where $\nu' \approx \nu$.

The total cross section obtained by integrating this cross section over angle is important in the attenuation of well-defined beams in passing through a material. The relative importance of

FIG. 2. Differential cross section for photons scattered at angles, θ , for a number of incident energies.

Compton scattering as compared to the photoelectric effect and pair production is illustrated for aluminum in Fig. 3 where the attenuation coefficient α is shown as a function of energy. The fraction of the photons surviving without an interaction upon passing through x g/cm² of aluminum is $e^{-\alpha x}$. The Compton effect is the major one between 0.5 and 2 MeV. Extensive tables and graphs for other elements are available.^{2,1}

FIG. 3. The attenuation coefficients, α , for the absorption of photons in aluminum as a function of energy. The broken lines represent the separate contributions of the photoelectric effect, the Compton effect, and pair production to the absorption.

In detectors whose response is proportional to the energy deposited by the recoil electrons, the distribution of electron energies associated with a photon of known energy is of interest. The distribution is given by the relation

$$\frac{d\sigma}{dT} = \frac{\pi r_0^2 mc^2}{(h\nu)^2} \left\{ 2 + \left(\frac{T}{h\nu - T} \right)^2 \left[\frac{(mc^2)^2}{(h\nu)^2} + \frac{h\nu}{T} - \frac{2mc^2(h\nu - T)}{h\nu T} \right] \right\}$$

where T varies from 0 to $T_{\max} = 2(h\nu)^2/(2h\nu + mc^2)$. A number of these distributions are shown in Fig. 4.

FIG. 4. The energy distribution of the Compton recoil electrons for several values of the incident photon energy $h\nu$. Based on figure in "Compton Effect" by R. D. Evans in "Handbuch der Physik," Vol. XXXIV, pp. 234-298, 1958, J. Fluge, Ed., by permission of Springer-Verlag, publishers.²

Scattering of Plane Polarized Radiation. The differential cross section for the scattering of plane polarized radiation by unoriented electrons was also derived by Klein and Nishina. It represents the probability that a photon, passing through a target containing one electron per square centimeter, will be scattered at an angle θ into a solid angle $d\Omega$ in a plane making an angle η with respect to the plane containing the electric vector of the incident wave.

$$\frac{d\sigma}{d\Omega} = \frac{r_0^2}{2} \left(\frac{\nu'}{\nu} \right)^2 \left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - 2 \sin^2 \theta \cos^2 \eta \right) \quad (9)$$

The cross section has its maximum value for $\eta = 90^\circ$, indicating that the photon and electron tend to be scattered at right angles to the electric vector of the incident radiation.

This dependence is the basis of several instruments for determining the polarization of photons. For example, it was used by Wu and Shaknov⁴ to establish the crossed polarization of the two photons emitted upon the annihilation of a positron electron pair; by Metzger and Deutsch⁵ to measure the polarization of nuclear gamma rays; and by Motz⁶ to study the polarization of bremsstrahlung.

Scattering of Circularly Polarized Radiation. The scattering of circularly polarized photons by electrons with spins aligned in the direction of the incident photon is represented by

$$\frac{d\sigma}{d\Omega} = r_0^2 \left(\frac{\nu'}{\nu} \right)^2 \left[\left(\frac{\nu}{\nu'} + \frac{\nu'}{\nu} - \sin^2 \theta \right) \pm \left(\frac{\nu}{\nu'} - \frac{\nu'}{\nu} \right) \cos \theta \right] \quad (10)$$

The first term is the usual Klein-Nishina formula for unpolarized radiation. The $+$ sign for the additional term applies to right circularly polarized photons. The ratio of the second term to the first is a measure of the sensitivity of the scattering as a detector of circularly polarized radiation and is shown in Fig. 5.

In practice, the only source of polarized electrons has been magnetized iron where 2 of the 26 electron spins can be reversed upon changing its magnetization. Although the change in the absorption or scattering is usually only a few per cent, this is often sufficient to get accurate and reliable measurements of circular polarization.

Cross sections for some practical arrangements and discussions of earlier work are presented by Tolhoek⁸. Applications to the determination of the helicities of photons, electrons, and neutrinos in confirming the two-component theory of the neutrino are reviewed in considerable detail by L. Grodzins⁹.

FIG. 5. The ratio of the partial cross section dependent on the spin orientation of the electrons to the average cross section as represented by the second and first terms of Eq. (10). Based on figure in "Compton Effect" by R. D. Evans in *Handbuch der Physik*, Vol. XXXIV, pp. 234-298, 1958, J. Fluge, Ed., by permission of Springer-Verlag, publishers.²

Proton and Deuteron Compton Effect. Particle-like scattering of high-energy photons by protons and deuterons has been observed and has been referred to as the proton and deuteron Compton effect. The kinematic equations are identical to those for electrons except that the mass is that of the proton or deuteron.

Although the cross sections are smaller than that for electrons, by the square of the ratio of the masses, the scattering is easily distinguished by the characteristically higher energy of the radiation at large angles. At energies above the pion threshold, the cross section is dominated by pion nucleon resonances. The experimental cross sections for the scattering by protons, as presented by Steining, Loh, and Deutsch,¹⁰ are shown in Fig. 6. Some experimental results and

FIG. 6. The differential cross section for the scattering of high-energy photons by protons at 90° in the center of mass system. Based on figure in Steining, Loh and Deutsch, *Phys. Rev. Letters*, **10**, 536 (1963).¹⁰

calculations on the coherent scattering from deuterium are described by Jones, Gerber, Hanson, and Wattenberg¹¹.

Computers may be mechanical, electromechanical, or electronic devices. They may operate in the analog or the digital mode, or a combination of the two. Whatever their form may be, their basic function is the automatic performance of a selected set of mathematical or logical operations.

Analog Computers. The analog computer (sometimes called the continuous computer), is often identifiable as a physical model of the problem to be solved. Problem data are represented by physical quantities like lengths, voltages, fluid densities, etc., and solutions are obtained through measurement of output quantities. A simple illustration is the slide rule which adds lengths representing the logarithms of the factors to give as the measure of a product a length representing its logarithm. Other illustrations are artificial transmission lines used to predict the performance of proposed electric power transmission lines, and electrical linear equation solvers. The former is a reduced scale model of the proposed power line; the latter is a model of the system of equations which consists of coupled circuits to represent the equations, electrical components to introduce the coefficients, and electrical meters to indicate the solution.

An analog computer may be a large device containing components which represent elementary mathematical functions and components which perform integration or differentiation. Devices of this type, called differential analyzers, have been used extensively for the solution of differential

equations. The first differential analyzer was designed by Vannevar Bush about 1930 and consisted of mechanical integrators of the wheel-and-disk type, a frame containing removable shafts, changeable gears and couplings, input handwheels and recording pens for producing graphs of problem solutions. Later Bush, Caldwell, and others developed more automatic differential analyzers in which the coupling between integrators was controlled by switching techniques enabling users to program on punched paper tape the interconnections of components to set the device up for problems. Still later the mechanical integrators gave way to electric integrators, and compact differential analyzers were developed consisting entirely of electrical circuitry and meters, with the exception of the input units.

Sophisticated computers have been built whose basic operation is straightforward counting. One such computer, the Maddida, appeared in 1951. It performed mathematical operations by reducing them to counts. It was characterized as a digital differential analyzer and was applied to the solution of differential equations. Its precision was higher than that within the realm of capability of analog computers.

Digital Computers. The digital computer, as its name implies, is an extension of finger counting. It is as old as the abacus, which has been in use for at least twenty-five centuries. And forerunners of the modern digital desk calculating machine were presented to the world by Blaise Pascal in France in 1642 and Gottfried Wilhelm Leibnitz of Germany in 1671. However, current emphasis on computer development and use is centered about a recently developed device, the automatically sequenced electronic digital computer.

In 1786, J. H. Müller, an engineer, conceived the idea of an automatic digital computer, but he was discouraged by the technical difficulties barring its development. About twenty-five years later, Charles Babbage, a young English mathematician, made suggestions for an automatic digital "difference engine" designed to build up mathematical functions automatically by the use of differences and to print the answers without human intervention, except to start the computation. Before completing this device, Babbage turned to a more general concept, called the "analytical engine," which was logically similar to the modern automatic digital computer. The analytical engine was not completed, although Babbage worked on it almost half a century until his death. The design requirements were beyond the purely mechanical techniques of his day.

A limited realization of Babbage's dream of a universal computer took place at the turn of the century, with the invention of punched-card methods in 1890 by Herman Hollerith. Electromagnetic techniques had been perfected which made possible the realization of Hollerith's ideas and led to the development of commercial punched-card accounting equipment of wide-

spread application. In this computing equipment data are represented by holes in punched cards and the sequence of operations is determined by the configuration of patch-cords in electrical plug boards.

Work was begun independently by both Howard Aiken and George Stibitz on automatic relay computers in about 1937. The ensuing computers embodied the dream of Babbage that was beyond the technical facilities available in his day—controls that provided for the automatic sequencing by punched cards or paper tape of all the operations required for the solution of a problem, including the acquisition of data, the calculations, and the recording of results. Some relay computers even had the ability to discontinue a problem and begin working on another, according to criteria introduced into the machine with the set of instructions, or program, inserted initially into the device.

The development of pulsed electric circuitry for RADARS made possible the utilization of the fast response of electronic tubes in computation. The first electronic digital computer, the Eniac (Electronic Numerical Integrator and Calculator) was developed under the leadership of John Mauchly and J. P. Eckert. Even though radar technology was then available, the use of electron tubes as relays was novel, and the reliability requirements on the electronic counting and switching circuits in the Eniac exceeded those of any prior application.

While the Eniac was an extremely fast computer, operating at the speed of electronic circuitry, it was sequenced through the setting and placement of hundreds of switches and electrical jumpers. Problem set-up time, even for calculations of only moderate complexity, could occupy days or even weeks, during which time the machine was not available for other use. The designers, not satisfied with this feature, were planning a more automatically sequenced electronic digital computer, called Edvac (Electronic Discrete Variable Automatic Computer), even before Eniac's completion. Edvac's design was the forerunner of the modern stored program, automatically sequenced electronic digital computer.

Functionally described, the present electronic digital computer comprises four components: an arithmetic or computing unit, a high-speed internal storage unit, input-output devices (which may be a single dual-purpose unit), and a control unit.

Data and instructions are indistinguishable within the electronic digital computer; both are represented for example by binary patterns of vacuum tube, transistor, or diode states in the electronic circuitry, and by such patterns of magnetized spots on small toroidal cores or thin magnetizable film in the high-speed storage. In the preparation of instruction sequences, called programming, the user must arrange to have the control unit refer to the correct locations in the high-speed storage for instructions. In addition, computers often contain auxiliary storage in the

form of magnetic tape or rotating magnetic drum.

For effective exploitation of its high operating speeds, the electronic digital computer contains built-in branching operations, which enable the control to select alternative paths according to the results of prior calculations. In addition to this flexibility, since instructions and data are indistinguishable in form, the arithmetic unit can modify the stored instructions by performing calculations on them. By employing these features, having received initially a complete set of instructions, electronic digital computers can solve without human intervention problems of tremendous complexity and magnitude. This characteristic has caused the devices to be called electronic brains and, more conservatively, stored-program computers.

The electronic digital computer is normally a high-precision device, capable of handling numbers of twelve-decimal digits or more in coded binary form or straight binary numbers of 35 bits or more. Theoretically the computer can provide whatever precision is required by distributing numbers over more than single registers, or single storage locations, and the use of special, multi-precision programs. In actuality multi-precision techniques slow down the computers to such an extent that rarely does one go beyond double-precision operation.

Numbers may be represented within the computer in logarithmic form, a mantissa together with the exponent of the power of the number base giving the appropriate scale factor. This representation simplifies programming by eliminating the need for insertion of scaling factors in programs to keep data from spilling off the computer registers. The logarithmic representation is called floating point representation. Floating point operation may be programmed on computers which do not have it as a built-in feature, but at significant loss in operating speed.

The set of computer instructions required for the solution of a problem, together with the numerical constants required, is called a "code" or a "routine." Routines may be built up from "subroutines" which are routines for frequently occurring calculations, ranging from the calculation of the trigonometric functions, logarithms, and exponentials to the solution of differential equations.

A commonly used form of computer instruction is the single-address instruction which designates the operation to be performed and the location, or address, of an operand in the internal storage. The second operand may be taken from a selected register, for example an accumulator register in the arithmetic unit. Unless otherwise specified by jump or branching instructions, the single-address computer executes serially the instructions placed in successive storage locations, called addresses.

A section of single address coding is illustrated by the following; where the operations are designated mnemonically, (AC) and (M) designate the contents of the accumulator register and internal storage location M respectively:

Address	Instruction	Operations performed
100	CLA 198	(AC) is replaced by (198), (198) is unaffected.
101	SUB 199	(AC) is replaced by (AC)-(199), which is (198)-(199).
102	TMI 250	If (AC) is negative, control takes next instruction from address 250, otherwise it takes the next instruction from address 103.

Suppose location 199 contains a measure of accuracy reached in a successive approximation process, computed according to the instruction code, and (198) is the relevant prescribed numerical bound, placed in the code by the programmer; and suppose further, that address 250 contains the first instruction of the approximation subroutine. Then this coding arranges for the computer to turn aside from a routine to perform successive approximation unless desired accuracy has been obtained. This illustrates the branching operating, without which automatic computing of only limited scope would be possible.

The main advantage possessed by the electronic digital computer is its high speed of operation. Arithmetic operations and transfer of information between electronic registers or between high-speed storage and the registers takes at most only a few microseconds. For this reason the computer may be designed to use iterative techniques to perform even basic operations, like the extraction of roots. And in successive approximation techniques a formula may be applied literally thousands of times to obtain the required accuracy, at no great cost in time. The development of computational techniques adapted to the characteristics of the high-speed digital computer, including study of the generation and propagation of error, has given rise to a new mathematical field, called numerical analysis.

Programming, the preparation of instruction sequences for electronic computers, has become a profession. The modern computer may have a hundred or more built-in operations, and programming in terms of the basic operations is usually replaced by use of sets of instructions more natural for the human programmer to use, called programming languages. Among the many such programming languages in use, prepared by computer users and manufacturers, three have been proposed as standards: ALGOL and COBOL, for scientific and business applications, respectively, and FORTRAN, devised for general use, but more suitable for engineering and scientific problems than business application. Special programs for conversion of programs written in such languages into sequences of built-in computer operations, called compilers or translators must be provided. Most manufacturers of electronic digital computers supply these programs with their equipment.

CONDENSATION

The condensation of a vapor to form a liquid, other amorphous phase or crystal generally occurs by the mechanisms of nucleation and subsequent growth. Nucleation is a thermally activated process which leads to a stable fragment of the condensed phase. In the absence of surfaces of certain condensed phases, reactive foreign molecules or other potent catalysts to the nucleation process, it is usually the slower step and occurs at an appreciable rate only under conditions considerably removed from equilibrium. For the usual case where nucleation catalysts are present, one characterizes the process as heterogeneous nucleation, but if there are no such catalysts at all, one speaks of homogeneous nucleation.

In principle, statistical thermodynamics would appear to offer the most attractive approach to nucleation rate theory. For example, Band¹ and Hill^{1a} have given formal treatments for the equilibrium concentration of clusters of molecules in a vapor. However, the internal partition functions have thus far eluded quantitative evaluation. Further, in the case of metallic systems, one has at present little knowledge of the electronic energy states in clusters containing only a few atoms.

Accordingly, even to the present day, most treatments follow that of Volmer² and co-workers who evaluated the free energy of formation of clusters by ascribing macroscopic thermodynamic properties to them. Thus the free energy of a droplet is described as the sum of a surface term (area times surface tension) and a volume term (volume times the negative bulk free energy change). An attractive feature of this approach is that it permits ready visualization of the origin of the free energy barrier to nucleation in terms of the maximum in the above sum as a function of size. However, a very unattractive aspect is that the calculated size of the critical nucleus, i.e., the cluster size at the top of the free energy barrier, is only about 100 molecules, which leads one to doubt the applicability of macroscopic concepts in the present examples. Nevertheless, following standard methods,³ this spherical-drop model leads directly to a rather simple expression for the rate of homogeneous nucleation of droplets from supersaturated vapor.

The remarkable agreement² of this macroscopic theory with observations of the critical supersaturations for appreciable nucleation rates of various liquids in cloud chambers stood for many years as the basis of our knowledge of nucleation. Then within the past five years, it was

established that most of the earlier data probably represent heterogeneous nucleation on an attenuated and unknown concentration of gaseous ions.⁴ In fact, it now appears that the only critical supersaturation data for homogeneous nucleation of droplets are those of C. T. R. Wilson⁵ and of C. F. Powell⁶ who reported a "fog limit"* for nucleation of water droplets at a supersaturation ratio of about 5.0 (275°K).† Also, further theoretical work⁴ has recently established that the external partition functions had been omitted from the macroscopic theory. When these contributions are included, the theory predicts a critical supersaturation ratio of about 3.0 for water vapor at 275°K, in poor quantitative agreement with Powell's observations.

A considerable amount of work has been done on the heterogeneous nucleation of metal crystals from thermal vapor beams onto substrates.⁴ Most theoretical approaches follow a macroscopic treatment similar to that outlined above, and quantitative agreement with observed critical supersaturations for appreciable nucleation rate is again not good. However, it has been established that in most cases nucleation occurs by the processes of adsorption, surface diffusion, and statistical fluctuation to form the crystalline nuclei. Also, the qualitative relationships between nucleation and epitaxial deposition are thought to have been reasonably well established.

Growth is the process by which the stable nuclei continue to grow and thereby consume the supersaturated vapor. In general, several mechanisms are involved in the growth process, and some of these are thermally activated. However, the free energies of activation are usually low, and hence most growth processes proceed at an appreciable rate even under conditions close to equilibrium where the gross evaporation flux almost equals the gross condensation flux. The first step in growth from the vapor is thought to be adsorption of the impinging molecule. The overwhelming bulk of both experimental and theoretical work⁴ indicates that the impinging atoms or molecules are in most cases thermally accommodated and adsorbed at the surface before being either reevaporated or integrated into the liquid or crystalline structure. In the case of liquids with asymmetrical molecules, Eyring¹ and co-workers have shown that there is an entropy contribution to the free energy of activation which tends to reduce the adsorption efficiency** and hence the condensation coefficient‡ to somewhat below unity.

In the case of liquids, it is thought that the molecular mobility is sufficiently high that the adsorbed molecules are taken almost immediately

* Denoting production of many droplets, i.e., of the order of 10^7 cm^{-3} .

† Meaning the ratio of actual to equilibrium partial pressure of vapor.

** Ratio of molecules which become adsorbed to those which impinge.

‡ Ratio of gross condensation to impinging fluxes.

into the liquid structure. However, the situation is quite different for crystals, whose surfaces are still most conveniently visualized in terms of the original "atomic building block" model of Kossel⁷ and Stranski.⁸ Thus, in the case of certain surfaces of high index, the kinks in the steps of the atomically rough surface provide ready sinks for adsorbed molecules. In fact, experiment shows that such planes grow so rapidly that they quickly eliminate themselves from the crystal growth form, leaving the smoother surfaces of low index. These closely packed planes contain no steps and kinks to serve as sinks for the admolecules diffusing on the surface. Accordingly for a perfect crystal, it is thought that growth can proceed only by nucleation of new monomolecular layers, whose edges provide the sinks, and their lateral propagation. A typical supersaturation ratio for appreciable growth by this mechanism is of the order of 1.5 for molecular substances, and there is a large amount of theoretical and experimental evidence⁹ for the general occurrence of this type of growth from the vapor at high supersaturations.

The fact that real crystals do indeed grow at much lower supersaturation ratios, of the order 1.01, continued to present a theoretical problem for many years. Then in 1949 Burton, Cabrera and Frank¹⁰ showed that certain emergent dislocations of the screw orientation* must provide a source of monomolecular steps for growth at low supersaturations. Further, they demonstrated that the resultant growth form on the close-packed surface, the growth spiral, cannot exterminate itself as do other types of steps or ledges. In the usual case, crystal growth by this mechanism is thought to be controlled by surface diffusion of the admolecules. Experimental verification of these predictions is now voluminous.¹¹

In the interests of brevity, the complex and interesting effects relating to diffusion in the vapor,⁴ gaseous ions,¹² adsorption of impurities,⁴ chemical reaction,⁹ and dissipation of the heat of condensation have been omitted from the above discussion.

CONDUCTIVITY, ELECTRICAL

The electrical conductivity of a material is a measure of its ability to carry an electric current. The conductivity σ of an isotropic material in a steady (dc) electric field E is defined by

$$j = \sigma E$$

where j is the current density (charge transported per unit time across unit area perpendicular to the current flow). In mks units (used throughout this article) j is measured in amperes per square meter and E in volts per meter, so that σ is in $(\text{ohm-m})^{-1}$ or mhos per meter. The reciprocal of the conductivity is the electrical resistivity, $\rho = 1/\sigma$. The electrical resistance R of a sample is the ratio of the potential drop across the sample to the total current through the sample. The resistance of a cylindrical sample (with the current flow parallel to the axis of the cylinder) is

$$R = \rho l/A$$

where l is the length of the cylinder and A is its cross-sectional area. If the dimensions are measured in meters and ρ is in mks units, the resistance is given in ohms. The reciprocal of the resistance is the electrical conductance.

Many homogeneous solids and liquids obey Ohm's law for sufficiently small electric fields. Ohm's law states that the current through a sample is proportional to the potential drop across the sample, and thus R , ρ , and σ are independent of the impressed electric field. Samples which do not obey Ohm's law are called *non-linear*; gases fall into this category, as do many important circuit elements such as vacuum tubes and transistors. Most metals obey Ohm's law for fields up to at least 10^8 volts/m, though under certain conditions, semiconductors have shown deviations from Ohm's law for fields as low as 10^{-2} volts/m.

The existence of a finite resistance means that the energy delivered by the electric field to the current carriers is dissipated, being converted to

heat (mostly energy of atomic vibrations). The rate of dissipation per unit volume is given by

$$\frac{1}{2} \rho j^2 = \frac{1}{2} \sigma E^2$$

and is called the Joule heat.

In some solids, the conductivity is *anisotropic*, i.e., the magnitude of j depends upon the direction of E as well as its magnitude, and j and E are not necessarily parallel. If Ohm's law is obeyed it becomes

$$j = \sigma \cdot E$$

where σ is a second rank tensor. Anisotropic solids include single crystals of materials which do not have cubic crystal structures, and polycrystalline aggregates of such materials in which there exists some preferred orientation such as can be produced by extrusion or cold rolling.

If the applied electric field varies sinusoidally in time (ac), the conductivity generally depends upon the applied frequency ν . Appreciable deviations from the dc value may appear for microwave frequencies or greater. In the microwave and optical range, it is common to identify $\sigma = 2\pi\epsilon_0\nu$ as the imaginary part of the *dielectric coefficient*, where ϵ_0 is the permittivity of free space $1/4\pi\epsilon_0 = 9 \times 10^9$ newton m²/coulomb². Thus σ is closely related to the absorption of electromagnetic energy.

Solids are usually classified as metals, semiconductors or insulators. Metals are characterized by an increasing resistivity with increasing temperature. Resistivities of metals at room temperature range from about 10^{-8} to 10^{-6} ohm-m. Semiconductors are characterized by a decreasing resistivity with increasing temperature (impure semiconductors may show this behavior only at high temperatures). Resistivities of semiconductors at room temperature range from about 10^{-3} to 10^{-7} ohm-m. Insulators share the same temperature behavior of resistivity as semiconductors, so that the difference between the two classes of materials is one of degree only. Generally, materials with room temperature resistivities greater than 10^7 ohm-cm are called insulators. Resistivities as high as 10^{18} ohm-m have been observed. There are some materials intermediate between metals and semiconductors. For example, the resistivity of manufactured carbon decreases with increasing temperature at low temperatures, and increases at high temperatures. The room-temperature resistivity is also intermediate, varying from 10^{-5} to 10^{-4} ohm-m depending upon conditions of manufacture.

Except in the case of some insulators, the current in solids is carried by electrons. Quantum mechanics has shown that not all the electrons in a solid are free to carry current. The conductivity depends upon the number of free carriers and their ease of motion. The latter factor is expressed by the mobility μ which is defined by

$$v_d = \mu E$$

where v_d is the drift velocity (average velocity of the free carriers produced by the action of the

electric field). The drift velocity is usually very much smaller than a typical carrier velocity v (the average of the magnitude of the carrier velocities). The conductivity is then given by

$$\sigma = ne\mu$$

where n is the density of free carriers (in m⁻³), e is the magnitude of the electronic charge (1.6×10^{-19} coulomb), and μ is in square meters per volt per second. If more than one group of carriers is present, the total conductivity is the sum of contributions from each group. Quantum mechanics has also shown that the mobility in a pure, perfectly regular crystal would be unlimited. The mobility is limited by the scattering of the carriers by deviations such as the thermal vibrations of the atoms, impurity atoms, or irregularities in the crystal structure such as vacancies and dislocations. A simple approximate theory of the mobility allows it to be expressed as

$$\mu = e\tau/4\pi\epsilon_0 m^* \quad e\lambda/4\pi\epsilon_0 m^* v$$

where τ is the relaxation time (roughly, the average time between the collisions which a carrier makes with the scattering centers), λ is the mean free path of the carriers, and m^* is the effective mass of the carrier (a concept which comes from the theory of energy bands in solids, see SEMICONDUCTOR). If more than one scattering process is involved, the reciprocal of the relaxation time (scattering rate) is approximately the sum of contributions from each process. At room temperature, mobilities range from very small values (such as 10^{-1} m²/volt sec) to 10^2 m²/volt sec, relaxation times range from about 10^{-14} second to about 10^{-12} second, and mean free paths range from about 10^{-9} meter to about 10^{-6} meter. One of the early triumphs of quantum mechanics was the explanation of why the mean free path can be so much larger than the distance between neighboring atoms (of the order of 10^{-10} meter).

In good metals, n is the density of valence electrons, and is thus independent of temperature (except for very small temperature dependence due to the thermal expansion). Because the electrons follow the *Fermi-Dirac* distribution law, the typical velocity v is the velocity at the *Fermi Surface*, which is large (usually about 10^6 m/sec) and independent of temperature. The temperature dependence of the conductivity is that of the relaxation time τ , and the approximate additivity of scattering rates due to different processes results in *Matthiessen's rule* which states that the resistivity is approximately the sum of a temperature dependent part R_T , due to scattering by lattice vibrations, and a part R_i proportional to the concentration of impurities and lattice defects. As the amplitude of the lattice vibrations increases with increasing temperature, the scattering effect and R_T increase. Above the Debye temperature θ (given by $k\theta = h\nu_m$, where k is Boltzmann's constant and ν_m is the maximum frequency of the lattice vibrations), R_T is proportional to the absolute temperature. At low temperatures, R_T is proportional to the fifth power of the absolute

temperature, and at all temperatures it is well approximated by the *Bloch-Grüneisen formula*. At very low temperatures (1 to 18°K), some metals become superconductors and all measurable resistance disappears (see SUPERCONDUCTIVITY).

Pure semiconductors at absolute zero temperature have no free electrons. As the temperature is increased, some electrons are excited to current-carrying states (in the *conduction band*). The states that are left unoccupied (in the *valence band*) are also free to carry current, and are called *free holes*. The concentrations of electrons and holes increase very rapidly with temperatures, causing the resistivity to decrease. The carrier concentration may be expressed as

$$n = f(T) \exp(-\Delta E/2kT)$$

where T is the absolute temperature, ΔE is the energy gap between the valence and conduction bands, and $f(T)$ is a slowly varying function of temperature. Extra carriers may also be provided by impurity atoms, *donors* contributing electrons and *acceptors* trapping electrons and producing holes. Very small impurity concentrations may make very large changes in resistivity. If most of the free carriers come from impurities, the semiconductor is called *extrinsic*; it is *n*(negative)-type if electrons predominate or *p*(positive)-type if holes predominate. If most of the carriers come from thermal excitation, the concentration of electrons and holes are about equal, and the material is called *intrinsic*. The rate of change with temperature of the mobility of a semiconductor is generally less than the rate of change of carrier concentration. The mobility is often represented by $\mu = cT^r$, where r varies from about -2.2 to +1.5 depending upon the particular material, concentration, and type of defects, etc. The conductivity of intrinsic material can also be expressed as

$$\sigma = g(T) \exp(-\Delta E/2kT)$$

where $g(T)$ is another slowly varying function of T . This equation is often used to analyze experimental data and find ΔE .

Insulators may be thought of as semiconductors with such large energy gaps that n is very small and the resistivity is very high. In addition, the ions in some insulating solids (such as the alkali halides) are free to move and carry a measurable current. The ions move by "hopping" into vacant lattice sites. As they must cross a potential energy barrier, the ionic mobility is proportional to an activation factor $\exp(-\epsilon/kT)$. The resistivities of such solids are of the order of 10^2 to 10^8 ohm-m at room temperature, but are as low as 10^{-3} to 1 ohm-m at elevated temperatures.

Another mechanism for electronic conductivity seems to operate in certain oxides and perhaps in some organic semiconductors. In this case, the electrons are localized and move by "hopping" in the same way as the ions in ionic solids. This phenomenon is currently being investigated.

Because the resistivity depends upon the state

of crystalline order, it is used as a tool in studying phase changes, such solid-liquid, order-disorder, magnetic, and crystal structure transitions. The resistivity of some materials is affected by pressure and mechanical strain. Many insulators and semiconductors exhibit the phenomenon of PHOTOCONDUCTIVITY, in which the absorption of light produces free carriers and increases the conductivity.

Many conductors show the phenomenon of *magnetoresistance*, which is the increase in resistance when the conductor is placed in a magnetic field. (A very few materials exhibit negative magnetoresistance, which seems to be related to inhomogeneous structure of the conductor.) The basic cause of the magnetoresistance is the Lorentz force, which causes the electrons to move in curved paths between collisions. Even for isotropic materials, the conductivity and resistivity must be taken as tensors in the presence of the magnetic field, called the *magnetoconductivity tensor* and the *magnetoresistivity tensor*. The off-diagonal elements of the magnetoresistivity tensor are related to the *Hall effect*. The on-diagonal elements for isotropic materials or for the magnetic field parallel to a crystal axis are usually called the longitudinal magnetoresistance (for the current parallel to the magnetic field) and transverse magnetoresistance (for the current perpendicular to the magnetic field). For small values of the magnetic field, the change in resistance is proportional to the square of the magnetic field strength. For large magnetic fields, the resistance may saturate (approach a constant value), continue to increase as the square of the magnetic field strength, or follow a more complicated behavior. The magnetoresistance ratio (change in resistance divided by the zero-field resistance) reaches only a few per cent for most materials, but at low temperatures for some materials, such as bismuth, approaches 10^6 . In general, the transverse effect is larger than the longitudinal one; the effect is larger in high-mobility materials and is largest for materials with more than one type of charge carrier. The magnetoresistance may be used in conjunction with the Hall effect to deduce the type, density, and mobility of charge carriers, and to obtain information about the FERMI SURFACE.

CONSERVATION LAWS AND SYMMETRY

Among the most basic of the laws of nature are the conservation laws. A conservation law is a statement which says that in a given physical system under specified conditions, there is a certain measurable quantity which never changes regardless of the actions which go on within the system. One of the tasks of physics is to determine what those special quantities are which do not change under a given set of conditions.

Three classical conservation laws are those of energy, momentum and angular momentum. Laws of this nature are postulated as a result of many measurements of the energies and momenta involved in reactions of all kinds. It is always found that within the limit of accuracy of the experiment, the amount of energy in the system after the reaction is the same as the amount of energy before the reaction. Prior to the development of elementary particle physics, there was much emphasis on transformation of energy between its various "forms," such as mechanical, electrical, thermal, etc. The modern viewpoint is that the macroscopic behavior of matter is the result of interactions between elementary particles and that these elementary interactions individually obey the various conservation laws. In its elementary form, the law of conservation of energy states that when two or more particles interact, the total energy (kinetic plus potential) is always a constant. When we say, for example, that the kinetic energy of a moving object has been transformed into the potential energy of a compressed spring, what we mean on a microscopic level is that the atoms of the spring have been pressed closer together so that there is a greater amount of potential energy in the electric fields between the atoms of the spring. This increase of potential energy is associated with an equal decrease in the kinetic energy of the object which caused the spring to compress.

An important function of the conservation laws is that they allow us to make many predictions about the behavior of a system without going into the mechanical details of what happens during the course of a reaction. They give us a direct connection between the state of the system before the reaction and the state after the reaction. In particular we can say that any action which violates one of the conservations laws must be forbidden.

With the development of the Lagrangian and Hamiltonian methods of solving physical problems, and particularly with the growth of importance of quantum mechanics, it has become clear that the conservation laws are closely connected with the concept of symmetry in space and time. This is based upon the fact that the interaction between two or more objects can be described in terms of a potential energy function. If the potential energy of the system is known for any position of these objects in space and time, then we can predict the future motions of the objects. However, certain predictions can be

made without going through a complete solution of the equations of motion. For example, it is found that if the potential energy does not depend explicitly on one of the space coordinates, then the momentum associated with that coordinate never changes—it is a constant of the motion.

The following examples illustrate the major types of "geometrical symmetries" encountered in classical physics.

(1) An object moves in a three-dimensional space where its potential energy is the same at every point. The expression describing the potential does not explicitly contain the coordinates x , y or z . That is, the system is invariant with respect to translation of the origin of the coordinate system in any direction. This symmetry is associated with conservation of linear momentum: the momentum in all three dimensions is a constant.

(2) An object moves in a world which is flat so that the force of gravity is in the vertical (z) direction. The potential depends only on the height of the object above the ground, but does not depend on its location in the horizontal plane; i.e., the potential is invariant to a translation of the coordinate system in the x - y plane. There is now symmetry in two dimensions, and momentum in the x - y plane is conserved.

(3) In the interaction between two spherical bodies, if the potential depends only on the distance between the bodies, then there is spherical symmetry. The system is invariant to a rotation of the coordinate system about any axis. In this case, two components of angular momentum are conserved: as the two bodies orbit around their common center of mass, the magnitude of their angular momentum is constant, while the plane of the orbit in space never changes.

(4) If the interaction between two objects does not depend explicitly on the time coordinate, then the actions which take place do not depend on when we start measuring time; i.e., the properties of the system are invariant with respect to a translation of the origin of coordinates along the time axis. This symmetry is associated with conservation of energy. Use of a four-dimensional coordinate system allows us to associate conservation of momentum and energy in a unified manner with the geometrical symmetry of space-time.

(5) Another conservation law known in classical physics is that of conservation of electric charge. Since electric charge comes in discrete quantities (there is no known way of breaking an electric charge down into bundles smaller than that contained in an electron), this law deals with the counting of objects, rather than with the measurement of continuous variables, such as momentum or energy. Conservation of electric charge means that the total number of electric charges (taking positive and negative signs into account) in a closed system never changes. This formerly meant that electric charge could not be created or destroyed. We now speak of the creation of charged particles, but the creation

of a positive charge must always be accompanied by formation of an equal negative charge (e.g., an electron-positron pair is created by a photon). Conservation of electric charge is associated with a symmetry property of Maxwell's equations known as gauge invariance, which states that the absolute value of the electrical potential (as opposed to the relative value) plays no part in physical processes. More recently, in the development of quantum mechanics, it appears that conservation of electric charge is connected with the fact that the properties of a system of particles do not depend on the phase of the wave function describing the system.

The conservation laws and the concept of symmetry have acquired new importance in the area of elementary particle physics. The conservation laws act as "selection rules" to determine which reactions may take place between the many existing particles out of the enormous number of otherwise conceivable reactions.

An important property of elementary particles is *parity*. Each particle has a parity number associated with it: either $+1$ or -1 , depending on the type of particle. In an assembly of particles, there is a total parity, which is the sum of the individual parities. If parity is conserved, then this total parity does not change during the course of the reaction. This property of matter is associated with the so-called mirror symmetry. All the laws of nature which possess this type of symmetry are such that if the words "right" and "left" are interchanged in the statement of the law, then the behavior of the system obeying these laws is unchanged. It was formerly believed that every natural law was of this type. As a result of this conservation of parity, it was believed to be impossible to describe the difference between "right" and "left" by the use of words alone. A famous paper by C. N. Yang and T. D. Lee in 1956 pointed out the fact that in a special class of reactions involving the "weak nuclear" interaction, parity need not be conserved. As a result of this, it was seen that the universe does possess an asymmetry between right and left and that it is possible to describe an experiment which will definitely distinguish between the directions "right" and "left" in this universe.

Another type of symmetry of importance in elementary particle physics is that entitled *charge conjugation*. This principle states that if each particle in a given isolated system is replaced by its corresponding antiparticle, then nobody will be able to tell the difference. For example, if in a hydrogen atom the proton is replaced by an anti-proton and the electron is replaced by a positron, then this antimatter atom will behave exactly like an ordinary atom, as long as it does not come into contact with ordinary atoms.

However, it turns out that there are certain types of reactions where this rule does not hold, and these are just the types of reactions where conservation of parity breaks down. For example, consider a piece of radioactive material emitting electrons by beta decay. The radioactive nuclei are lined up in a magnetic field which is produced

by electrons traveling clockwise in a coil of wire, as seen by an observer looking down on the coil. Because of the asymmetry of the radioactive nuclei, most of the emitted electrons travel in the downward direction. If the same experiment were done with similar nuclei composed of antiparticles and the current in the magnet coil consisted of positrons instead of electrons, then the emitted positrons would be found to travel in the upward, rather than in the downward, direction. Interchanging each particle with an antiparticle has produced a change in the experiment.

However, the symmetry of the situation can be restored if we interchange the words "right" and "left" in the description of the experiment at the same time that we exchange each particle with its antiparticle. In the above experiment, this is equivalent to replacing the word "clockwise" by "counterclockwise." When this is done, the positrons are emitted in the downward direction, just as the electrons in the original experiment. The laws of nature are thus found to be invariant to the simultaneous application of charge conjugation and mirror inversion.

Other more technical conservation laws play a role in elementary particle physics. *Conservation of baryon number* and *conservation of strangeness* are rules required to account for the fact that certain reactions involving heavy particles are forbidden. *Time reversal invariance* describes the fact that in reactions between elementary particles, it does not make any difference if the direction of the time coordinate is reversed.

It is a temptation to say that "nature likes symmetries" in order to prove the necessity of a conservation law. However, to avoid pitfalls it must be realized that it is human beings who like symmetries. While a symmetry idea may first suggest a conservation law, the conservation law must be tested by experiment to see if the symmetry is valid.

CONSTANTS, FUNDAMENTAL

It is basic to the structure of modern physical theory that physical quantities such as the rest mass of the electron or the speed of light in vacuum have fixed and unchanging numerical values. It is also true that our knowledge of the numerical magnitude of these values is variable and, in general, changes with each new measurement which is made. For example, measurements of the velocity of light made over the past century have yielded results which have varied over wide ranges. This has even led some theorists to suggest that the velocity of light may in fact not be an exact constant but might have periodic variations with periods of several years. Not only does such a suggestion violate established theories of relativity, but it also violates the experimental evidence of a host of well-established indirect experiments. As a result of these indirect experiments, one can only conclude that it must be the experimental technique which is variable, rather than the speed of electromagnetic radiation. The uniqueness of the magnitudes of such quantities as the charge and mass of the electron or of Planck's constant of action has been well established by various indirect measurements and is fundamental to the current structure of physical theory. One can say that the existence of unique magnitudes is a characteristic of the fundamental nature of these concepts.

Fundamental Units. The numerical values of the fundamental constants are closely related to the question of units and standards, and it has long been suggested that fundamental physical constants be used as standards for physical units. It has been recognized that a fundamental physical quantity as a unit of length, for example, would be conceptually much better than the arbitrary unit of the foot or the meter. It is possible to consider as an appropriate unit of length the Bohr radius, $\hbar^2/4\pi^2me^2$, or alternately the Compton wavelength of the electron, h/mc . Because of the limitations of physical measurement, the use of such fundamental standards of length would be less accurate than other possible standards. However, the use of a physical unit rather than a completely arbitrary one (such as a standard meter bar) has the advantage of unique reproducibility and universal availability, and the unit of length is defined in terms of the wavelength of the electromagnetic radiation arising from the optical transition $2p_{10} - 5d_5$ in the isotope of krypton of mass 86. In terms of the wavelength of this radiation, the meter is now defined as 1650763.73 wavelengths, and the foot is defined by International agreement among all of the English-speaking nations to be exactly 0.3048 meters.* The unit of time (the second) is defined in terms of the tropical year, although the definition of the second in terms of the frequency of some atomic standard is being seriously considered and one strong front-runner in this race is the frequency of the hyperfine splitting in

hydrogen gas as maintained in the hydrogen maser. This frequency is perhaps one of the most accurate physical measurements known today $\nu = 1420405751.800 \pm 0.028 \text{ sec}^{-1}$ †

Experimental Determinations. The experimental determination of the numerical values of the physical constants is uncertain and variable if we confine our attention to the limits of experimental capabilities. The difficulties inherent in measuring physical constants to an accuracy of a few parts per million are great. Direct measurements of the mass of the electron or of the electronic charge are not as accurate as measurements which determine instead various combinations of these quantities. Whereas Millikan was able to measure the elementary charge on an electron in 1912, to one part in a few thousand (and this experiment can hardly be improved upon today), our current knowledge of the electronic charge, with an accuracy of approximately 1 part in 100,000 comes from combining measurements of the Sommerfeld fine structure constant with the gyromagnetic ratio of the proton, the Faraday constant, the magnetic moment of the proton relative to the Bohr magneton, and a half-dozen or so other measurements which affect the final result to a greater or lesser degree. In fact, the present knowledge of the numerical values of all of the so-called fundamental constants of physics come from such indirect measurements. Of these physical constants, only the universal gravitational constant, G , is measured independently of the others. It is true, in the first place, that no theoretical relation is known which relates G to the physical constants and, in the second place, that the accuracy with which G is known is several orders of magnitude poorer than the accuracy of the atomic constants.

With the growth in our knowledge of natural laws and of the technical means of making precise physical and chemical measurements, an increasing number of relationships have been discovered between the fundamental constants of physics and chemistry. At the present time, the situation regarding our knowledge of these constants can be considered as resembling a multidimensional bridge truss made up of elastic members, in which the length of each member represents the experimentally measured relationship between constants, and the stiffness is a measure of the

† At its meeting of October 6, 1964, the Twelfth General Conference on Weights and Measures adopted the following definition of the second of time in terms of the "atomic clock", superseding the previous astronomical definition in terms of the length of the mean solar year. "The standard to be employed is the transition between the two hyperfine levels $F = 4, M_F = 0$ and $F = 3, M_F = 0$ of the fundamental state $^2S_{1/2}$ of the atom of cesium 133 undisturbed by external fields and the value $9\,192\,631\,770$ hertz [cycles per second] is assigned." To within the accuracy of the respective measurements, this does not entail any change in the size of the second, but does provide a more accurate and more easily usable standard by which to measure the length of a second.

* Thus the English-speaking world uses the metric system for standards, if not for units.

accuracy of this measurement. The problem is to determine the positions of the nodes of this network. Furthermore, the alteration of any one member will produce an effect which will be transmitted throughout the entire structure. This will be true whether we change the length of a member, or its stiffness, or remove it entirely.

In order to determine the values of the physical constants from such an overdetermined set of data, it has become common to use the method of least squares. This can be considered as equivalent to the problem of minimizing the stored potential energy in our multidimensional framework. The fundamental requirement, however, is basically one of establishing a method of analysis which is consistent and independent of the choice of variables used to describe the situation. The method of least squares not only does this but also provides a procedure which yields "best" values of the constants in the sense that these values are the most accurate. For these reasons, least squares adjustment has been used for all of the significant determinations of the values of the fundamental physical constants over the past 15 years. The unit of mass and the unit of temperature, however, are still defined in a completely arbitrary manner—the unit of mass, in terms of the mass of the prototype kilogram, and the unit of temperature, as $1/273.16$ of the absolute thermodynamic temperature of the triple point of pure water.

Numerical Values. Because the numerical values are the result of a least squares adjustment, care must be used in computing the standard deviation of quantities whose values are not given in a table. Because of the interdependence of the numerical data, the errors are strongly correlated. The errors in these constants may be either greater or less than those computed by simple propagation of error, depending on whether the correlation is positive or negative. Thus the relative uncertainty in a computed constant not given in a table can be obtained only from a calculation which includes the full variance matrix of the least squares adjustment. For more

complete details on the point, see "Present Status of our Knowledge of the Numerical Values of the Fundamental Physical Constants," E. Richard Cohen and J. W. M. DuMond, Second International Conference on Nuclidic Masses, Vienna, Austria, Springer-Verlag, 1964.

constants. Most of these values have been recommended for general use by the U. S. National Academy of Sciences, National Research Council Committee on Fundamental Physical Constants (1963), and have been adopted by the U. S. National Bureau of Standards.

In these Tables, the figures in parentheses represent limits of error taken to be three times the standard deviation calculated in the least squares adjustment. If it were safe to assume that the error distributions are gaussian, these error limits would represent a range such that there was

a probability of only 1 chance in 400 that the correct value would lie outside those limits. The use of three standard deviations is justified in this case, however, because of uncertainties regarding systematic errors and/or theoretical inadequacies in the interpretation of the experimental data. All of the data in these Tables which depend upon molecular weights are expressed on the unified scale adopted in 1960 by the International Union of Pure and Applied Physics and the International Union of Pure and Applied Chemistry. This scale was based on the arbitrary assignment of the

mass of exactly 12 units to the isotope ¹²C. As such, this definition replaces both the physical scale of atomic weights based on the assignment of mass 16 to the isotope ¹⁶O and the chemical scale of atomic weights which assigns the mass 16 to the "natural" isotopic mixture of oxygen isotopes.

E. RICHARD COHEN

CORIOLIS EFFECT

A marksman fires his rifle due north. In the absence of wind, he might well expect it to travel in a straight line and land due north of him. But will it? The physicist would, in general, answer no on the basis that the earth is rotating and is not, therefore, an inertial frame of reference (see ROTATION—CIRCULAR MOTION). G. G. Coriolis first analyzed this effect in 1844, and he is acknowledged in its name. For large artillery projectiles this effect may be significant, but for hand carried weapons it is usually negligible. For instance, a typical .22-caliber rifle bullet might be horizontally deflected one foot in traveling a mile.

That a projectile will normally follow a path which is curved in the horizontal leads conversely to the idea that to follow a straight path over the rotating earth requires the application of a side-wise force. Even though this appears to violate Newton's first law (see DYNAMICS), it is perfectly true in a non-inertial system—hence, the reason that this force is sometimes called "fictitious."

A body which is moving with constant speed in a straight line in an inertial system is not accelerating and is subject to no net force. An observer in a rotating coordinate system will, however, observe the same object to follow a curved path. The observer may treat this apparent deflection from a straight line as an acceleration which is always perpendicular to the path of the object. It is called the Coriolis acceleration. The

apparent force applied to the body to cause the deflection from a straight path into a curve is called the Coriolis force.

The true acceleration of a body moving with constant speed in a straight line in a rotating coordinate system is equal in magnitude to the apparent acceleration just described. An expression for it may be derived simply and quite rigorously, but not generally, for the case of a body moving with constant radial speed in a rotating system. It consists of two distinct components both easily evaluated for the case mentioned. One component arises from the change in direction of the radial velocity of the body, the other from its change in tangential velocity due to changing distance from the center of rotation (see ROTATION—CIRCULAR MOTION).

Suppose the rotating system has a constant angular velocity ω , and the body moves radially with constant speed v . It is initially at distance r_1 from the center of rotation with velocity \vec{v}_1 . After a small time interval Δt , it is at distance r_2 with velocity \vec{v}_2 (see Fig. 1). The two velocities \vec{v}_1

FIG. 1.

and \vec{v}_2 are related since the final velocity \vec{v}_2 is the vector sum of the initial velocity \vec{v}_1 and the change in velocity $\Delta \vec{v}$. Refer to Fig. 2 for a vector diagram of the preceding statement (see STATICS). If we consider instantaneous values, Δt approaches zero, the angle $\omega \Delta t$ approaches zero, and the chord Δv approaches its arc in length. We may then use the well known angle-arc relationship (arc length) = (radius) (angle in radians), and write

$$\Delta v = r \omega \Delta t, \text{ or } \Delta v / \Delta t = \omega v$$

Now $\Delta v / \Delta t$ is the acceleration component (a_1) resulting from the change in direction of \vec{v} .

The tangential velocity of a body equals the product of its angular velocity and its radius of rotation. Equating changes in these quantities yields

$$\Delta v_t = \omega(r_2 - r_1) = \omega \Delta r$$

FIG. 2.

Or, dividing by Δt

$$\Delta v_1 / \Delta t \rightarrow \omega \Delta r / \Delta t$$

Now $\Delta v_1 / \Delta t$ is the acceleration component (a_2) arising from changing tangential velocity, and $\Delta r / \Delta t$ is the radial speed v . Hence a_2 also equals ωv .

Since both a_1 and a_2 lie in the same direction, being perpendicular to the radial velocity and to the right in the figure, their magnitudes may be added together with the sum equaling the magnitude of the Coriolis acceleration a_c

$$a_1 + a_2 = a_c = 2\omega v$$

Using Newton's second law $F = ma$, the Coriolis force is

$$F_c = 2m\omega v$$

The earth is not, of course, a rotating plane. The Coriolis acceleration reaches a maximum at the poles and vanishes at the equator. If v_h denotes horizontal velocity on the earth's surface, the resulting Coriolis acceleration may be evaluated by reference to Fig. 3 where ϕ is the latitude and v is the true radial speed with respect to the earth's axis.

$$v/v_h = \sin \phi$$

$$v = v_h \sin \phi$$

and the Coriolis acceleration becomes

$$a_c = 2\omega v_h \sin \phi$$

and the Coriolis force is

$$F_c = 2m\omega v_h \sin \phi$$

The Coriolis effect applies to any object moving on the surface of the earth, and a more general treatment will show it to be completely independent of the direction of motion. The quantity $2\omega \sin \phi$ is commonly known as the Coriolis parameter. Since the earth rotates 2π radians in 24 hours, or at a rate of 7.27×10^{-5} radians/sec, the parameter is quite small, and equals exactly 10^{-4} sec^{-1} at about $43\frac{1}{2}^\circ$ latitude. This small value

for the Coriolis parameter means that in everyday life its effects are small and go largely unnoticed. For instance, the Coriolis force on an automobile driving at turnpike speeds might typically be one pound. The acceleration can cause considerable deflection of long range artillery, however, and appropriate corrections must be made.

The Coriolis effect plays a large role in the great mass movements of the oceans and atmosphere. In the northern hemisphere, the apparent deflection is always to the right of the direction of motion. For example, air drawn toward a center of low pressure is deflected to the right and eventually flows around the low pressure area in a counterclockwise motion. This motion characterizes frontal storms typical of temperate climates. If the pressure force and Coriolis force are equal, the resulting wind velocity is said to be geostrophic (i.e., "turned by the earth"). The wind velocity in large storms above several thousand feet elevation is closely geostrophic.

FIG. 3.

Though it has been only a little over a century since the first analysis of this effect, the Coriolis force has through the centuries influenced man's environment through its control of the motions of winds and waters, and hence the distribution of the sun's heat over the earth. Ancient man, not aware of the motion of his planet, was nevertheless profoundly influenced by it.

COSMIC RAYS

Cosmic rays are conventionally divided into two classes: primary and secondary. The former are, for the most part, energetic charged particles of extraterrestrial origin, while the latter are the products resulting from collisions of the primary cosmic rays with atoms of the earth's atmosphere.

The Primary Radiation. The primary cosmic radiation is quite striking in four respects: the primary intensity is essentially constant in time, isotropic in space, anomalous in composition, and it contains very energetic particles indeed.

Present-day measurements indicate that with the exceptions of the local perturbations discussed under solar effects, the primary cosmic-ray intensity exhibits less than 1 per cent variation in time. In fact, measurements of radioactivity produced in meteors by cosmic rays show that the intensity has not appreciably changed in the last several million years.

Isotropy simply means that there is no direction or directions in the sky from which the bulk of cosmic radiation emanates; this includes the direction of the sun. Since there are magnetic fields of varying magnitude and direction throughout interstellar space which deflect charged particles, the isotropic nature of the primary intensity is not too surprising. For one can say that, owing to "collisions" of the cosmic rays with these fields, the primary particles lose their "memory" of the directions to their source. Magnetic fields also act in other ways. For example, the earth's field effectively prevents particles of less than 10^8 eV energy from reaching the earth at all (1 eV 1.6×10^{-19} joule). Moreover, there is some indication that cosmic rays between 10^{14} and 10^{18} eV may be very slightly guided along the field lines of the local spiral arm of our galaxy. It should be remarked that the diameter of the orbit of a proton of 10^{18} eV moving in the galactic magnetic field would be comparable with the thickness of the galactic disc, so that above 10^{18} eV such guidance is impossible.

The total number of primary cosmic rays striking the earth's atmosphere is roughly $1 \text{ cm}^{-2} \text{ sec}^{-1}$. These particles are mostly protons, but decreasing proportions of heavier atomic nuclei are present ranging from helium (15 per cent of the proton intensity for the same momentum-to-charge ratio) all the way to iron. Although there are many interesting features of the primary composition, one of the most notable is that the abundance of the elements in cosmic rays is very different from the chemical composition of the sun. Not only are cosmic rays relatively rich in heavy nuclei, but there is roughly one million times as much lithium, beryllium, and boron in cosmic rays as in the sun. These light elements presumably arise from collisions of heavy nuclei with interstellar matter. Such considerations determine a value of a few grams per square centimeter for the average amount of matter traversed by cosmic rays before reaching the earth. This, in turn, gives a mean lifetime of cosmic rays in the galaxy (density

$\sim 10^{-26} \text{ g/cm}^3$) on the order of 10^8 years or $\sim 10^6$ years in the spiral arms.

The spectrum of cosmic ray energies between 10^{14} and 10^{19} eV is a power law relation given by $N(>E) = 3 \times 10^{-10} E^{-(1.7 \pm 0.1 \log_{10} E)} (\text{cm}^2 \text{ sec steradian})^{-1}$ where E is the energy in 10^{15} eV. This spectrum should not be extrapolated beyond the indicated upper limit since some experiments indicate a possible change in the slope beyond this point. The maximum particle energies which have been detected are well in excess of 1 joule. These are truly phenomenal energies, equivalent to taking all of the kinetic energy of an apple dropped a distance of several meters and giving it to just one proton of the apple's atoms. Not only are some cosmic rays individually energetic, but because of their high spatial density, cosmic rays represent a large fraction of the total energy associated with astrophysical phenomena. The energy density of cosmic rays, optical photons, interstellar magnetic fields, and the turbulent motions of interstellar matter are each about equal to 1 eV/cm^3 .

The Origin of Cosmic Rays. In the half-century since their discovery by Hess in 1911, the problem of the origin of cosmic rays has remained largely unsolved. The major difficulty has been that of finding a satisfactory mechanism whereby charged particles can be accelerated to the very high energies just discussed. Our sun is wholly inadequate in this respect; the sun fails on all four counts mentioned previously to be considered as the sole source of cosmic rays.

Present-day speculation considers the sources to be violently active celestial objects; exploding galaxies and exploding stars or supernovae. There are several reasons why such objects may indeed be the long-sought sources. For one thing, supernovae are known to be rich in heavy elements. For another, both types of explosive phenomena involve huge amounts of energy. This is inferred from the presence of synchrotron radiation (the emission of electromagnetic waves by electrons moving in magnetic fields) which implies in some instances electron energies as high as 10^{13} eV. These electrons are most likely the decay products of mu-mesons which are again the decay products of charged pi-mesons. The pi-mesons are created in nuclear interactions, thereby suggesting the presence of very energetic nuclei, some of which could escape from the magnetic fields of the supernovae to become cosmic rays. There are possibilities of verifying such a model, for neutral pi-mesons should also be produced in the nuclear interactions. These mesons decay into gamma rays which travel in straight lines unaffected by magnetic fields. Thus, experiments to detect high-energy gamma rays coming from supernovae and radiogalaxies will be of much aid in solving the long-standing problem of cosmic-ray origin.

High-energy photons have already been observed in the primary cosmic rays. Gamma and x-rays produced by interaction of primary particles with interstellar matter and optical photons (inverse Compton scattering) give information on the distribution and composition of

matter in our galaxy. Also, several point sources of x-rays have been discovered, one of which is in the Crab Nebula. The processes whereby these x-rays are created are not yet known.

All high-energy interactions lead ultimately to the production of neutrinos. Although the detection of primary neutrinos will be terribly difficult, neutrino astronomy would be a useful tool for the study of astrophysical phenomena.

Solar Effects. Although the sun has little effect on the high-energy cosmic-ray flux, it strongly influences the low-energy flux during the occurrence of solar flares. At such periods of solar activity protons may be emitted by the sun with kinetic energies of nearly 10^{11} eV. The accompanying increase in the sea-level cosmic-ray intensity can be as much as fifty times larger than the normal value of about $1.0 \text{ cm}^{-2} \text{ min}^{-1}$.

The earth is surrounded by electron ring currents circulating in the earth's magnetic field. These ring currents, which are named Van Allen belts after their discoverer, contain electrons with energies ranging from 10^3 to 10^5 eV. Occasionally, the sun emits an ionized gas which moves outward with a velocity of 10^3 km/sec. These particles do not have enough energy to penetrate the earth's magnetic field, but they do modify the field, thereby releasing electrons trapped in the Van Allen belts. When the electrons strike the atmosphere, the resultant ionization produces auroras. The magnetic fields associated with the ionized gas also prevent low-energy galactic cosmic rays from reaching the earth. The accompanying decreases in the sea-level cosmic-ray intensity are known as Forbush decreases. Since these fluctuations in intensity are related to solar activity, their occurrence is periodic and associated with the 11-year solar sunspot cycle.

The Secondary Radiation. If it were not for the secondary cosmic rays, high-energy primaries would never have been discovered. Consider a particle detector of area 1 cm^2 and aperture 1 steradian. With such a detector one must wait nearly 10^{10} years, the lifetime of the universe, before registering the passage of a 1-joule particle. As we shall now see, the detection frequency is enormously enhanced by the earth's atmosphere.

The layer of air above the earth represents about 13 collision mean free paths for an incident proton. After the inevitable interaction of a primary particle with some atom high in the atmosphere, the nuclear debris so produced undergoes successive interactions with air atoms further down in the atmosphere. In each collision pi-mesons are created which decay as described earlier into mu-mesons and gamma rays. Owing to their large Lorentz factors commensurate with their high energies, the mu-mesons continue on down to sea level before decaying. The gamma rays, on the other hand, produce electron-positron pairs which, in turn, radiate more gamma rays. The huge number of electrons created in this way is called an extensive air shower (EAS). After reaching a maximum at an atmospheric depth dependent on the energy of the primary particle,

the EAS slowly decays by ionization losses. Even so, energetic primaries can give rise to EAS which contain billions of electrons at sea level. The total number of EAS particles reaching sea level is nearly proportional to the primary energy, the relation being roughly 10^9 to 10^{10} primary eV per secondary electron.

As they cascade down through the atmosphere, the electrons are scattered by air atoms so that, upon reaching sea level, the EAS electrons and positrons are distributed over a large area. The density distribution of these secondaries is peaked around the shower axis (the direction of motion of the primary particle) and decreases monotonically with distance in a plane perpendicular to the shower axis. For example, a 1-joule primary can create detectable numbers of electrons per square meter even at distances of 1 km from the shower axis. Thus, a small number of detectors spread out in a plane can (a) detect EAS produced by energetic primaries, (b) give information concerning the primary energy from knowledge of the secondary electron density distribution, and (c) be used to determine the incidence angle of the primary particle. The last measurement involves timing the arrival of the shower front (the nearly plane surface containing the majority of the secondaries and propagating along the shower axis with the velocity of light) at several distances from the shower axis. By spreading a dozen or so detectors over an area of 10^6 square meters, several showers representing primaries of 1 joule or more can be detected per year.

In order to extend the detectable upper limit of primary cosmic-ray energies, other techniques are in use which effectively increase the sensitive area of the individual detectors. These methods involve the detection of the atmospheric fluorescence produced isotropically (hence detectable over a wider area than the electrons themselves) by the secondary electrons as they pass through the atmosphere.

Among the many uses of the secondary radiation has been the discovery of new particles, notably the positron and the various mesons, and the study of their interactions with matter. In addition, some of the interactions provide remarkable clocks for finding the age of many terrestrial features. For example, the collisions of secondary neutrons with atmospheric nitrogen produce carbon-14 which combines with oxygen to form radioactive CO_2 , thus facilitating the familiar technique of radiocarbon dating developed by Libby.

COSMOLOGY

Cosmology is the study of the structure and evolution of the universe in the large. The observable universe consists of a hierarchy of stars, galaxies and clusters of galaxies, the latter having typical dimensions of about 1.6 megaparsecs* (Mpc) or 5 million light-years, and containing a few hundred members. It is still in dispute as to whether there are clusters of clusters of galaxies or even higher-order structure. It is generally considered that the space between galaxies and clusters is permeated with a tenuous gas. However, this has not been directly observed and only crude limits can be put on the amount and physical state of the intergalactic medium. The smoothed-out density of the matter which is observable in the form of galaxies is about 5×10^{-30} g/cm³. The total density, including the unobserved intergalactic matter could be two or three orders of magnitude higher than this.

It was discovered about forty years ago that the lines in the spectra of galaxies are redshifted with respect to their terrestrial wavelengths and that the red shift increases linearly with increasing distance. It is generally supposed that this is due to the Doppler effect and that, consequently, the universe is expanding. It is held by a minority that the universe is static and that photons lose energy while traversing the intergalactic medium by physical processes which are not yet understood. The rate at which the apparent velocity of recession increases with increasing distance is known as Hubble's constant, H . Current observations indicate the H is about 100 km/sec/Mpc; this value could be wrong by as much as a factor of two. The most distant known galaxies have redshift $\Delta\lambda/\lambda \approx 0.5$ and lie at distances of roughly 1000 Mpc, or 3 billion light-years.

Theoretical cosmologists investigate the properties of idealized "world models" in which, for example, the observed patchy distribution of matter is replaced by a smoothed-out distribution. In order to construct the mathematical models, simplifying assumptions must be made, and the uniqueness of the universe, coupled with the fact that we have only been able to survey a small part of it, means that these assumptions are only partly based on observation. The most

generally adopted assumption is the "cosmological principle"—that the universe has the same general character as seen from any point within it at a given time. A more powerful assumption, the "perfect cosmological principle," that the universe has the same general character as seen from any point *at any time*, forms the starting point of the steady-state cosmology proposed by Bondi and Gold in 1948. In this theory, matter is supposed to be continually created throughout the universe so as to exactly balance that lost by the observed expansion. Thus, cosmology is not, strictly speaking, a branch of physics because although the prediction of a particular cosmology must be consistent with the laws of physics as we know them locally, the cosmologist does not always start by extrapolating these known laws to the large scale.

Probably the first attempt to apply modern ideas to the universe as a whole was made by Olbers in 1826. Olbers assumed that space is Euclidean, that it is filled with stars whose average number per unit volume and whose average luminosity are constant throughout space and time, and that there are no large-scale systematic motions of the stars relative to one another. He was then able to show that if the universe has infinite extension in space and time, the radiation density at any point should equal that at the surface of a typical star! This result was a paradox to Olbers and the paradox remained unresolved until the discovery of the expansion of the universe one hundred years later.

The first dynamical models of the universe were derived after the publication of Einstein's General Theory of Relativity in 1915. This theory, with its idea that space is only locally Euclidean and that the presence of matter influences the curvature of space, made it possible to devise world models which are isotropic and finite in volume but which have no boundary in the sense that a light ray can travel on and on indefinitely. It is also possible to construct expanding or contracting models in which the density of matter and radiation remains uniform but a function of the time and in which there is no preferred center of expansion. Thus the space between clusters of galaxies is imagined to expand or contract in a manner similar to the behavior of a uniform distribution of points on the surface of an expanding or contracting balloon.

We now describe some of the main world models which have resulted from solutions of the field equations of general relativity. In 1916, Einstein devised a static model of the universe in which the density is uniform and in which space is so curved that the universe has a finite volume. In order to obtain this solution and to overcome certain mathematical difficulties, Einstein had to incorporate an additional term, known as the cosmological constant, into his equations. This term represents a repulsive force between masses which increases with their separation. This term has a negligible effect on terrestrial phenomena and on the motions of the planets, but it can have an important effect on the cosmic

* A parsec is the distance at which the radius of the earth's orbit around the sun subtends an angle of one second of arc. It approximately equals 3×10^{18} cm.

scale and, in Einstein's static universe, the repulsive term just balances the gravitational attraction.

In 1917, de Sitter found a further solution of Einstein's equations for a universe of vanishingly small density. It represented an expanding universe in which test particles of negligible mass would recede from one another with ever increasing velocity. It was just at this time that astronomers were discovering the red shift of the galaxies, and de Sitter's model, although it represented a universe having zero mass, helped to establish the idea of an expanding universe.

In Einstein's static model, the equilibrium between the gravitational attraction and the cosmical repulsion is unstable. Thus a slight contraction of the universe would lead to the gravitational attraction dominating the repulsion and the universe would continue to contract, and vice versa. On this basis, Lemaître and Eddington were able to devise a universe having an infinite past in the unstable Einstein state until some unknown effect started off the expansion which would then go on at an ever increasing rate.

In all the theories, with the exception of the steady-state theory, the age of the universe (i.e., the time which has elapsed since the beginning of the expansion) is of the order of the reciprocal of Hubble's constant. The currently adopted value of $H = 100 \text{ km/sec/Mpc}$ leads to a "Hubble time" of about 10^{10} years. The measurement of the Hubble constant is technically very difficult and depends in essence on measuring the *apparent* luminosity of an object of known *intrinsic* luminosity. Distances to galaxies within a few megaparsecs can be measured by using cepheid variable stars for which there is a relation between the period of light variation and the intrinsic luminosity; this relation can be calibrated using cepheids in our own galaxy. Unfortunately, distances within our own galaxy are difficult to measure accurately; hence, until recently, the adopted value of Hubble's constant was about 500 km/sec/Mpc . This led to a "Hubble time" of less than 2×10^9 years whereas the earth is known to be about 3.5×10^9 years old! In order to avoid a situation in which the solar system is older than the whole universe, cosmological theories have been devised, principally by Dirac, by Jordan, and by Dicke, in which the universal constants (for example, G , the constant of gravitation) are functions of time. The time-scale problem is now less serious, but the astrophysically determined ages of the oldest star clusters in our galaxy come out to be about 16×10^9 years, or almost twice the Hubble time. This discrepancy is generally not considered serious in view of the large uncertainties in the age dating of star clusters and the measurement of Hubble's constant.

However, if the age discrepancy persists it will be strong evidence in favor of the steady-state theory of Bondi and Gold, in which the universe has an infinite past and an infinite future. In this theory, the loss of matter by the expansion of the universe is exactly compensated by the creation of new matter so that the formation of new

galaxies is always going on and only the *average* galaxy need have an age equal to the Hubble time. The steady-state theory has also been vindicated to some extent by recent work on the origin of the elements. It is known that most of the mass of the universe is in the form of hydrogen, the simplest and lightest element, and until about 1950, it was generally considered that conditions necessary for the synthesis of the heavier elements could only have existed in some primeval compact state of the universe before the expansion began. However, it has now been shown that element building can go on inside stars during the normal course of their evolution and that, indeed, the primeval gas out of which our galaxy formed was almost pure hydrogen.

The original form of the steady-state theory was later elaborated by Hoyle who added additional terms to the field equations of general relativity to represent the creation of matter. In 1963, Hoyle and Narlikar advanced a new version of the theory which is claimed to incorporate Mach's principle—the idea that the inertia of a body is due to its interaction with distant parts of the universe. Failure to incorporate Mach's principle has long been considered to be a major drawback to the cosmologies based on the conventional field equations.

On the observational side the major step forward in recent years has been the discovery that many of the radio astronomical sources are extremely distant abnormal galaxies. This has led to the discovery of the most distant known galaxies and to attempts to decide between the various cosmological models by examining the way in which the number of sources increase with decreasing luminosity. The first indications were that the data favors an evolutionary rather than the steady-state cosmology, but this cannot be confirmed until more is known about the intrinsic distribution in luminosity of the radio galaxies.

CRITICAL MASS*

The mass of fissionable material required to produce a self-sustaining sequence of fission reactions in a system (a reactor, for example) is the *critical mass* for that system.

* Research sponsored by the USAEC under contract with Union Carbide Corporation.

The chain of reactions will be self-sustaining if, on the average, the neutrons released in each fission event initiate one new fission event. The system is said to be *critical* when that condition exists.

Neutrons released from fissioning nuclei may escape from the system; they may be captured in non-fissioning reactions, or they may produce new fissions. The critical mass depends on the relative probabilities of these processes and on the average number of neutrons released per fission. Evaluation of these probabilities is the concern of criticality calculations which are important in the design of neutron chain reactors.

The escape probability becomes larger for smaller systems, inasmuch as the ratio of surface to volume increases as a system is made smaller. Thus, there is a *critical size* below which the chain reaction in a given system cannot be made self-sustaining. The concept of critical size is often discussed along with critical mass.

Neutrons colliding with non-fissionable nuclei in the system may be absorbed and thus lost to the chain reaction. In fact, not every neutron absorption by a fissionable nucleus results in a fission. Non-fission absorption must be taken into account in calculating the critical mass. For example, a system containing pure U^{235} can be made to have a low critical mass. If the same configuration were loaded with a sufficient quantity of natural uranium (0.0057 per cent U^{233} , 0.72 per cent U^{235} , and 99.27 per cent U^{238}) to contain the same total amount of U^{235} , it would not be critical because at certain energies the U^{238} readily absorbs neutrons without fissioning.

The probability that a neutron striking a fissionable nucleus will cause it to fission depends on the fission cross section (see FISSION) which in turn depends on the energy of the neutron, increasing as the neutron energy gets lower. Thus the addition of a moderator, that is, a material which takes up energy from the neutrons without absorbing them, will lower the critical mass of a system. Water and carbon are good moderators.

The critical mass also depends on the average number of neutrons released per fission. This number changes slightly with neutron energy. For U^{235} it is about 2.45 for thermal neutrons and about 2.65 for 1 MeV neutrons. The numbers are slightly higher for U^{233} .

A complete criticality calculation must take into account the fission cross section as a function of neutron energy and the average neutron yield per fission as a function of neutron energy. Also to be considered are the geometrical distributions in the system of the fissionable nuclei, the absorbing nuclei, and the moderator, and how the neutrons scatter from these. Furthermore, the configuration of reflecting material outside of the fuel volume has a marked influence on the critical mass. A complete calculation would construct the spatial and energy distributions of neutrons in the system through the use of a mathematical procedure that models the history of neutrons from their release to their capture or escape. Neutron diffusion theory or transport theory is usually used

for such calculations. Actual calculations use idealizations and produce approximate results. Often, criticality experiments are required to verify results.

Finally, as examples of critical masses, a sphere 32 cm in diameter containing U^{235} dissolved in water has a critical mass of about 2.1 kg. The same sphere with U^{233} has a critical mass of about 1.1 kg.¹ The Oak Ridge National Laboratory graphite reactor was loaded with 31 tons of natural uranium. This contains about 203 kg of U^{235} .

A thorough discussion of neutron chain reactors is given in reference 2.

CROSS SECTION AND STOPPING POWER

Cross section, σ , is a conceptual quantity widely used in physics, particularly in nuclear physics, to represent the probability of collision between particles. For example, if a beam of neutrons (n) is incident from the left on a nucleus (A), a certain fraction of the neutrons will be removed from the beam by interaction with A.

By definition, σ is the fraction of neutrons, contained in 1 cm² of beam, that interact with A.

For a thin layer of material of thickness dx containing N nuclei/cm³ the number of nuclei/cm² is $N dx$. If the flux of incident neutrons is ϕ /cm², the fractional decrease in traversing the thin layer will be:

$$-(d\phi/\phi) = N\sigma dx \quad (1)$$

or for a finite thickness x and incident flux ϕ_0 :

$$\phi = \phi_0 e^{-N\sigma x} \quad (2)$$

For a given type of nucleus there are, in general, a number of possible interactions, a, b, c, \dots . The total cross section σ_t is the sum of the cross sections for the individual interactions:

$$\sigma_t = \sigma_a + \sigma_b + \sigma_c \dots \text{etc.} \quad (3)$$

A convenient unit for nuclear cross sections is the *fermi* or *barn*, an area of 10^{-24} cm², which is approximately equal to the cross-sectional area of medium weight nuclei.

The *stopping power*, Sp , of a material for an incident particle is the quantity $-dT/dx$, i.e., the energy loss per unit length of path, generally expressed in ergs per centimeter. This type of attenuation is used primarily in considerations of the passage of heavy charged particles, such as protons, deuterons and alpha particles, through matter. For example, for a particle of any spin having a rest mass $M(\gg m_0)$, the rest mass of an electron), charge ze , and velocity $V(=\beta c)$, the energy loss (as excitation and ionization) per element of path $-dT/dx$ to a homogeneous medium containing N atoms cm⁻³, each of atomic number Z , is given by:

$$-\frac{dT}{dx} = \frac{4\pi e^4 z^2}{m_0 V^2} NZ \left[\ln \frac{2m_0 V^2}{I} - \ln(1 - \beta^2) - \beta^2 \right] \quad (4)$$

where I is the mean atomic excitation potential calculable from the Thomas-Fermi electron distribution function to be $I = kZ \approx 11.5$ electron volts.

The *relative stopping power* S is the inverse ratio of the length of a material to the length of a standard substance having equivalent stopping power (usually referred to aluminum as $S_0 = 1$) at 15°C and 76 cm pressure:

$$S = \frac{(dT/dx)_1}{(dT/dx)_0} = \frac{N_1 B_1}{N_0 B_0} = \frac{\rho_1 B_1 A_0}{\rho_0 B_0 A_1} \quad (5)$$

where ρ is the density, A the atomic weight, and $B = Z \ln 2m_0 V^2 / I$ from Eq. (4).

CRYOGENICS

Cryogenics is the production and study of phenomena which occur at very low temperatures, i.e., below about 80°K. The first step in attaining the required temperature generally involves the liquefaction of a gas or gases. Liquids can exist over a range of temperatures limited by the critical point at the higher end and the triple point at the low-temperature end. It is thus possible to compress a gas to the liquid phase at the critical point and to cool it by boiling under reduced pressure to its triple point. A series of gases having their critical and triple points overlapping can thus be used in a cascade process each being used as the refrigerant for the next in the series. Pictet used this method to liquify oxygen, using methyl chloride and ethylene as refrigerants. There are however no liquids which cover the range from 77°K to the critical point of hydrogen or from 14°K to the critical point of helium (5.2°K). Thus liquid hydrogen and helium cannot be produced by the cascade method.

A gas may also be cooled by making it do work in the course of an expansion. When an ideal gas is expanded through an aperture into a constant volume, no work is done, since there are no interactions between the molecules and the molecules themselves occupy no volume. When a nonideal gas is so expanded, however, an amount of internal work ($W = (PV)_{\text{final}} - (PV)_{\text{initial}}$) is done against the intermolecular forces; this work may be positive or negative, resulting in a cooling or heating of the gas. Air is cooled by this Joule-Thomson expansion at room temperature, but hydrogen and helium must be precooled to 90 and 15 K to obtain further cooling upon expansion. Using this method, Kamerlingh Onnes first succeeded in liquefying helium in 1908. Compressed gases may also be made to do external work, for example by expansion against a movable piston. In this case the work is always positive and helium may be cooled and liquefied without any pre-cooling by liquid hydrogen. The marketing of a machine of this type designed by Collins has given a great impetus to low-temperature research.

With liquid helium readily available in the laboratory, research in the temperature range 5 to 0.8 K has become commonplace. By using the isotope of helium He³, it is possible to attain temperatures down to about 0.3 K. Since He³ is relatively rare it is used in small closed systems and is pre-cooled by He⁴ which is at about 1 K. Reduction of the pressure over the liquid He³ can cool it to about 0.3 K since it has a lower boiling point than He⁴. This is about the lowest temperature that can be attained by boiling liquids at reduced pressure, and to reach lower temperatures it is necessary to use magnetic phenomena.

It was pointed out by Debye and Giauque that at 1 K the entropy of paramagnetic salts was still fairly large and, moreover, that it was almost all due to nonalignment of magnetic moments and that the entropy of lattice vibrations was very small. If the electron spins are aligned by application of a magnetic field, the entropy of the salt drops to a low value and the heat of magnetization can be extracted isothermally. The salt can then be thermally isolated and demagnetized adiabatically and its temperature will fall. Temperatures in the order of 0.01°K can readily be reached by this method, and the lower limit for a single demagnetization would seem to be about 10^{-3} K. When demagnetization occurs, the spin system reaches equilibrium temperature in about 10^{-10} seconds. It is found that equilibrium is achieved between the spin temperature and the lattice temperature by spin-orbit coupling in times in the order of a few seconds. Paramagnetic salts have relatively high specific heats at low temperature, and hence the cold salt can be used to cool other bodies; however, making good thermal contact to the cooled salt can be difficult.

Kurti, Simon and Gorter suggested that a further reduction in temperature could be attained if adiabatic demagnetization was performed on nuclear moments rather than the electron spin. The temperature which can be reached in an adiabatic demagnetization is determined by the

point at which the entropy of the system in zero external field decreases sharply with decrease in temperature due to the alignment of magnetic moments, i.e., the point at which the interaction energy μh equals kT (h = internal field, μ = magnetic moment). Since the interaction energies of nuclear moments are much smaller than electron-spin interactions, much lower temperatures should result. The materials used experimentally were metals cooled to 10^{-2} °K by contact with a paramagnetic salt. The thermal isolation of the nuclear spins during demagnetization was achieved naturally by the nuclear spin-conduction electron relaxation time (~ 100 seconds). Thus while the nuclear spins cooled to between 10^{-5} and 10^{-6} °K, the conduction electrons and lattice remained in thermal contact with the cooling salt at 10^{-2} °K. Kurti postulates that cooling of the lattice to 10^{-4} °K might be possible if suitable thermal switches can be devised.

Another method of attaining temperatures below 1°K is to use the fact that the entropy of a superconducting metal is less than that of the metal in its normal state. Quenching of a superconductor by the application of a magnetic field can cause a cooling to about 0.1°K. However, since the specific heat of metals is very small at these temperatures, they are not very suitable for cooling other bodies.

Measurements of low temperatures are usually carried out using secondary thermometers which have been calibrated at certain fixed points previously determined on the absolute scale by a standard instrument. This instrument is generally a constant-volume gas thermometer used at low pressures. When the readings of this instrument are extrapolated to zero pressure, the scale coincides with the thermodynamic scale. In the range 0.8° to 5.2°K, the vapor pressure of He¹ provides the most commonly used secondary scale and it agrees with the absolute scale to within 2 millidegrees over this range. The use of He³ instead of He⁴ increases the coverage to 0.3°K.

Resistance thermometers are useful over a wide range; for example, platinum is used from 273 to 15°K, and carbon covers the range 20 to 2°K and has the advantage of being quite insensitive to magnetic field. The above are examples of secondary standards where the scales are interpolated between fixed points. For temperatures below 0.3°K the susceptibility of a paramagnetic salt can be measured and the temperature calculated by extrapolation from Curie's Law $\chi = C/T$. This method gives true values for the temperatures as long as Curie's Law holds. Beyond this region, it is necessary to perform a thermodynamic cycle to determine the relationship between the magnetic temperature T^* and the absolute temperature T . The method of Kurti and Simon is to demagnetize adiabatically from a known temperature on the absolute scale, using a number of different field intensities, and hence to determine the relationship between T^* and the entropy S over the required range of temperature. Measurement of the amount of heat Q necessary to raise the temperature from T^*_1 to T^*_2 gives the absolute value

of the average temperature T_{12} from the relationship $\Delta Q = T \Delta S$. The heat is generally supplied to the salt by gamma rays, thus ensuring even heating of the sample, a necessary precaution since the thermal conductivity is poor. The problem of nonlinearity does not arise in the case of nuclear spin demagnetization since in this case the susceptibility obeys Curie's Law down to 10^{-7} °K.

One of the most interesting phenomena of cryogenics is that of SUPERCONDUCTIVITY, which was also discovered by Kammerlingh Onnes. When metals are cooled from room temperature, their resistivities decrease and at low temperature, they attain low values which are fairly independent of temperature. Some metals, however, have a critical temperature below which their resistance goes to zero. Such a metal is known as a superconductor. In a single crystal of tin, for example, the transition from normal to superconducting may take place in less than a millidegree. If a current is induced in a loop of a normal metal, it decays with a time constant determined by the inductance and the resistance of the loop. In the case of a superconductor, induced currents have been observed to flow for years without any measurable decrease. Since the resistance of a superconductor is zero, the electric field inside it must be zero; hence, from Maxwell's equation $\text{Curl } \mathbf{E} = -\partial \mathbf{B} / \partial t$, we know that \mathbf{B} cannot change inside a superconductor. In fact it has been shown that \mathbf{B} is zero throughout a superconductor. When a superconductor is placed in a magnetic field, supercurrents flow in such a way as to exclude the magnetic field, hence a superconductor is a perfectly diamagnetic body with $\chi = -1/4\pi$. A superconducting material below its critical temperature can be returned to the normal state by a magnetic field (which may be externally applied or may be due to a current flowing in the superconductor). Another property of superconducting metals is the fact that their thermal conductivity is about 1000 times less than that of the same metal in the normal state. Thus superconductors can be used as thermal switches by quenching them with magnetic fields.

An interesting phenomenon which takes place at low temperature is that of superfluidity in liquid helium. As liquid helium is cooled below 2.18°K, it undergoes a sudden discontinuity of specific heat and a second-order transition to the superfluid state. In this state the viscosity of the helium becomes a function of the method used to measure it. Measured by an oscillating disc method, the viscosity falls from 23×10^{-6} poise just above the transition to 1×10^{-6} poise at 1.3°K. Measured by passage through very fine capillaries the viscosity is very nearly zero in the superfluid state. Hence, it is postulated that there are two coexisting non-interacting fluids, one having the properties of non-"superfluid" helium and the other having virtually zero viscosity and zero entropy. It is interesting to note that the thermal conductivity of superfluid helium is about 2000 times greater than that of copper; this is the result of motion of the entropy-free superfluid

rather than normal thermal conductivity (see SUPERFLUIDITY).

The use of magnetic properties in cooling has already been mentioned. There are several fundamental experiments on the magnetic properties of materials which become possible as a result of the low-temperature environment available. The first of these was discovered by deHaas and Van Alphen in 1930. They found that at low temperatures, the susceptibility of bismuth single crystals rose and fell periodically as the magnetic field was increased. Later work has shown that the periodicity occurs in all metals at low temperatures and is the result of quantization of electron motion perpendicularly to the applied field. This effect has recently been used to determine the Fermi surface of metals.

The method of alignment of nuclear moments has been used to study radioactive decay as a function of nuclear orientation. The aligning field in this case can be either an externally applied magnetic field or an internal crystal field. One of the more striking of these experiments has been the test of the Lee-Yang theory of non-conservation of parity in weak interactions. A third fundamental experiment of interest was the confirmation of London's idea that flux through a superconducting ring is quantized. The ring was in fact a lead tube of 10^{-3} -cm diameter, and it was suspended from a torsion balance. The tube was made superconducting in the presence of longitudinal magnetic fields, and the frozen-in flux was measured and found to be quantized.

In addition to the fundamental aspects of cryogenics, several practical applications of low-temperature phenomena have recently been developed. The most striking of these is the superconducting magnet. To achieve magnetic fields in the order of 70 kilogauss by normal methods calls for the expenditure of about a megawatt of power for as long as the field is maintained. The necessity of removing this power by circulation of cooling fluids adds to the inefficiency. When a superconducting coil is used in the persistent current mode, no energy is needed to maintain fields of this magnitude. These magnets have been made possible by the discovery of alloys such as Nb_3Sn and Nb-Zr which have the capacity to remain superconducting while they are subjected to high magnetic fields and are carrying the current necessary to produce the field. A second practical result has been the development of superconducting circuitry. The basic device in this area has been the cryotron, a switch in which the field resulting from current in a superconductor can quench another superconducting superconductor to its normal state. When made in the form of deposited thin films, cryotrons have switching times less than 10^{-8} seconds. The use of thin-film cryotron circuits represents the first attainment of the all-thin-film integrated circuit.

CRYSTALLIZATION

The forms of natural crystals have been studied by mineralogists for many years and have been classified by symmetry, interfacial angles, perfection of shape, and more detailed criteria. These forms are often related to the molecular structure and growth of the crystals. The equilibrium shape of a crystal is that for which the surface energy is a minimum. Since atomic planes of densest packing usually have the lowest surface energy, these planes predominate in the surface facets of equilibrium crystals, resulting in a correspondence between the atomic structure and shape of the crystal. However, natural and even synthetic crystals rarely have the equilibrium shape, because for crystals larger than about 10μ in dimension, the differences in surface energy between faces are too small to transport enough material over the distances required. Therefore the morphology of crystals is usually determined by the rate of crystal growth, rather than by the equilibrium shape.

A crystal is bounded by those faces whose rate of growth is slowest, since fast-growing faces grow out of existence. Close-packed planes frequently grow most slowly, so even when kinetic factors control the crystal shape there is usually a relation between the faces of a crystal and its molecular structure.

Crystals can be grown from the vapor, liquid, or solid phase. Experiments show that crystals form initially in tiny regions of the parent phase and then propagate into it by accretion of material. Thus nucleation and subsequent growth, rather than uniform transformation throughout the parent phase, is the usual mechanism of crystallization.

The formation of a minute crystalline region in a parent phase below its transformation temperature is driven by the difference between the actual and the transformation temperature; however, this formation is opposed by the necessary creation of surface between the crystal and the parent phase. When the volume of a crystalline embryo fluctuates to a value large enough so that this opposing surface energy is overcome, the resulting crystalline nucleus grows. Crystals almost always nucleate on foreign material, such as container walls or impurity particles, because a foreign surface reduces the surface energy for nucleation.

Since crystallization proceeds by propagation of the nucleus into the parent phase, the surface separating these phases is the site of incorporation of molecules into the crystal. If this surface is perfectly smooth, incorporation of molecules into the crystal is difficult; however, if there is a monomolecular step on the surface, incorporation

will occur preferentially at the step. Such a step contains kinks or jogs, which are the final sites for incorporation. Thus the progress of a molecule from the parent phase into the crystal is: (1) transport through the parent phase to the crystal surface, (2) adsorption onto the crystal surface, (3) movement on the surface to a step (surface diffusion), (4) adsorption onto a step, (5) transport along the step to a kink, and (6) incorporation at the kink. Steps (2), (4) and (6) can involve reorientation and desolvation of the molecules. The rates at which crystals grow can be controlled by any one or several of these steps. The rate of removal of the heat of transformation from the crystallizing interface can also influence the over-all growth rate.

Under certain extreme conditions the surface of a crystal is "rough," so that molecules can be incorporated anywhere on it. However, these conditions are rarely encountered, and normally molecules are incorporated only at steps. If the crystal surface is molecularly perfect, a pillbox of material must be nucleated on it to create a

step, which then grows to another perfect surface. Under these circumstances, continued surface nucleation is required, and growth occurs only below a certain undercooling. However, experimentally, crystals often grow at much smaller undercoolings than this calculated one, so that a continuous source of steps must exist. For this source F. C. Frank^{7, p. 48} postulated a screw dislocation in the crystal that emerges at the crystal surface. This emergent dislocation provides a step pinned at one end, so that as it propagates it winds up into a spiral and is always available for incorporation of molecules. Many spirals have been observed on crystal surfaces; one is shown in Fig. 1. The surface nucleation and screw dislocation mechanisms for crystal growth were definitely confirmed by the elegant experiments of G. W. Sears on the growth of perfect metallic filaments ("whiskers"), metallic platelets, and paratoluidine crystals.⁸

Impurity molecules can modify the morphology and growth rate of crystals by their effects on the relative surface energies and growth rates of

FIG. 1. Growth spiral on a paraffin crystal, observed by C. M. Heck. From Doremus, Roberts and Turnbull "Growth and Perfection of Crystals," by permission of John Wiley & Sons, Inc., New York.⁷

different crystal faces. These molecules can poison growth on certain planes by adsorption at kinks in steps on these planes, slowing the growth of these steps. Impurities can also change the rates of adsorption and surface diffusion of incorporating molecules. The rate of pillbox nucleation can be increased by the lowering of surface tension by impurity adsorption. Therefore impurities can produce different crystal habits and either faster or slower growth rates.

To make crystals for laboratory and industrial use a great variety of techniques have been used. Growth by either condensation or chemical reaction from the vapor phase can give crystals with high purity and special structures and forms. For large-scale industrial use, this method is too costly, although it is valuable for certain special applications. Luminescent crystals of zinc and cadmium sulfides are grown from the vapor for industrial use. Metallic crystals with few impurities and defects, and in the special forms of thin films or whiskers, can readily be grown from the vapor. Other crystals made in this way are silicon, germanium, iodine, selenium, phosphorus, and a variety of organic crystals. The study of the growth of ice crystals from water vapor has special importance in meteorology.

The most common method of growing metallic and semiconducting crystals is by solidification of their melts. Special techniques have been developed to grow single crystals of these materials and many others. In the Czochralski method, a seed crystal is touched to the melt, and the crystal is "pulled" from it by slowly withdrawing the seed. In the Bridgman technique, the melt is slowly moved through a temperature gradient in a furnace, so that crystallization starts at one point in the melt and propagates through it relatively slowly. In the Verneuil method, powder is added to the molten surface of a crystal so that a crucible of other material is not needed. This method is used for materials with high melting temperatures, such as alumina, spinels, rutile, mullite, ferrites, and yttrium-iron garnet. Solid crystals are often purified by zone melting, in which a molten zone is moved through the crystal. Segregation of impurities into the melt purifies the crystal.

Precipitation from liquid solution is a common method of growing crystals. Ionic salts are grown from aqueous solutions both industrially and in the laboratory. Sugar is crystallized from water solution. Other organic crystals, including polymers, are grown from a variety of solvents. Quartz crystals are grown from aqueous solution at elevated temperatures and pressures ("hydrothermal growth"). Various crystals have been grown from more exotic solvents, for example: garnets, titanites, and ferrites from molten salts ("fluxes") tin, iron, and phosphorous from mercury, and diamond from a molten metal under pressure.

Crystallization from the solid phase is also possible. Growth of grain size in a single-phase solid, called recrystallization, is often used to improve the properties of polycrystalline mate-

rials, particularly metals. Crystalline compounds can be made from high-melting materials by pressing together mixtures of their powders and diffusing them together at high temperature ("sintering"). Crystals can be grown from a solid solution. This type of precipitation is frequently used to improve the properties of metals, for example, to harden them.

CRYSTALLOGRAPHY

Crystallography is the science of the geometric properties of matter in the ordered solid state. When atoms or molecules condense into a solid phase from a liquid or gaseous phase, the lowest energy state is achieved if they become arranged in as regular a way as possible, usually by forming a small basic unit of structure which is repeated indefinitely in three dimensions throughout the solid to form a *crystal*. The geometric properties of this unit and its manner of regular repetition are highly characteristic of the substance in question, and constitute an exceedingly useful subject of study in connection with any field of science involving the solid state. Occasionally, no extended, regular repetition of structure is present

in the solid phase, but this glassy state has many properties of a liquid and lies outside the realm of crystallography. In other cases, extended order may occur in one direction only (as in fibres) or in two directions (as in some clays), but by far the most common condition of the solid state is full three-dimensional order, and it is with this type of order that crystallography is primarily concerned.

The familiar outward manifestation of the three-dimensional order of the atomic structure of the solid is the polyhedral shape commonly exhibited by crystals. These remarkable shapes were admired for centuries (see, for example, Albrecht Dürer's engraving "Melancholia," 1514), but the underlying principle governing them was first discovered by Steno in 1669. This principle is expressed as the Law of the Constancy of Interfacial Angles, according to which the dihedral angles between the faces of all crystals of a given substance remain unchanged regardless of how the relative sizes and shapes of the faces may vary. René Just Haüy in the late eighteenth century was the first to present a systematic account of the characterization of substances by the measurement of interfacial angles, that is, crystallography, and thus establish it as a science. Haüy was a mineralogist, and through his influence crystallography was subsequently developed and applied by workers mainly in mineralogy, and to a small extent in chemistry. The link between external form and internal structure was dramatically completed by M. von Laue's discovery of x-ray diffraction in 1912, and from then on crystallography was rapidly developed and advanced in physics laboratories, and later more and more in chemistry.

A crystal may or may not exhibit external faces, but if it does, these may be studied in terms of their distribution and development, which constitutes the *morphology* of the crystal, by special techniques of *crystallography*, usually making use of an instrument that reflects beams of light from the crystal faces into a telescope, the *two-circle goniometer*. If the crystal has no faces, its internal geometric properties may be studied by its interaction with radiation, by the methods of *optical crystallography* if refraction of infrared, visible or ultraviolet light is involved, or by *x-ray crystallography* if diffraction of x-rays (also neutrons or electrons) is studied.

The crystal can be defined completely (except for chance irregularities and defects) in terms of the arrangement of the atoms within a finite unit of volume called the *unit cell* (whose size is usually of the order of 10\AA on an edge) and the way this unit is repeated in three dimensions to fill up the volume of the crystal. The shape and dimensions of the unit cell provide parameters characteristic of the substance and constitute the first primary geometrical property of crystals. The most general unit cell (triclinic case) is a parallelepiped which can be defined by six constants, three edge lengths (a , b and c) and three interedge angles (α , β and γ). This unit cell is repeated by *translation*, a shift along each of the cell edges by an integral number of edge lengths. If the unit cell and its contents are

represented by a point in space, the crystal consists of a regular array of such points called a *lattice*, in which each point is related to every other by an integral number of vectorial translations corresponding to the unit cell edges. The lattice should be distinguished from the *crystal structure*, which refers to the arrangement of atoms within the unit cell, although the term "lattice" is sometimes loosely used in reference to the structure.

The atoms within the unit cell may be related to each other by a number of geometric operations called *symmetry*, and this phenomenon constitutes the second chief geometric property of crystals. The unit cell must embrace all of the different types of atoms related by symmetry that are not related by simple translation. On the other hand, the symmetry operations which apply to one unit cell are also operated on by the lattice translations, so that these symmetry operations must also apply to the entire crystal. Thus, the morphology of the crystal and all its other properties must obey this symmetry. The detection and definition of the symmetry also serve to characterize the substance and are equally as important in crystallography as the measurement of the lattice parameters.

The way in which symmetry operations can interact consistently with each other is strictly limited by the geometry of coincidence and can be rigorously analyzed by the mathematical methods of group theory, both as to what symmetry operations are possible and how they may be combined. The problem is usually approached by constraining all symmetry operations to pass through a single point in space, but special restrictions are introduced by the requirement that this point must be consistent with any point in the crystal lattice, that is, the symmetry groups must be consistent with the translational operations of the lattice. An important symmetry operation is the axis of rotation by which any motif is reproduced by a rotation around an axis of $360/n$ degrees, where n is the order of the axis. n successive operations then superimpose the object on itself. In crystals, because of the requirements of the lattice, n can only have the values 1, 2, 3, 4 and 6. A 5-fold axis is not possible, for example, for the same reason that it is not possible to fit regular pentagons into a regular two-dimensional pattern which will fill all space. Further, there are only 11 ways to combine the 5 axes together at a point; these are called the 11 axial point groups. These form a convenient basis for classifying all crystals into 6 *crystal systems*, which, while not strictly rational in their definition, provide a fundamental link between the symmetry of the crystal and its dimensional properties. Reference axes are generally chosen parallel to lattice translation directions, of course, but further, they are customarily taken parallel to prominent symmetry axes. Four of the axial point groups, for example, have a single 3-fold axis or 6-fold axis, with or without a number of 2-fold axes at right angles to them. In all these, the reference c axis is customarily set parallel to

TABLE 1. THE SIX CRYSTAL SYSTEMS

System	Independent Lattice Parameters	Axial Relationships	Number of Symmetry Groups			
			Axial Point Groups	Point Groups	Bravais Lattices	Space Groups
Triclinic	$a, b, c, \alpha, \beta, \gamma$	none	1	2	1	2
Monoclinic	a, b, c, β	$\alpha = \gamma = 90^\circ$	1	3	2	13
Orthorhombic	a, b, c	$\alpha = \beta = \gamma = 90^\circ$	1	3	4	59
Tetragonal	a, c	$b = a$				
		$\alpha = \beta = \gamma = 90^\circ$	2	7	2	68
Hexagonal	a, c	$b = a$				
		$\alpha = \beta = 90^\circ$	4	12	2	52
		$\gamma = 120^\circ$				
Cubic (isometric)	a	$b = c = a$				
		$\alpha = \beta = \gamma = 90^\circ$	2	5	3	36

the unique 3- or 6-fold axis, and the other two axes a_1 and a_2 , which are equivalent by symmetry, are taken normal to the c axis along lattice directions 120° apart, coincident with the 2-fold axes if present. These groups are all included in the hexagonal system.

The axial symmetry operations are operations of the first kind, that is, they reproduce left-hand motifs as left-hand motifs. Other symmetry elements of the second kind, that is, which reproduce left-hand motifs as right-hand motifs, are the center of symmetry and the mirror plane of symmetry. When these operations are added to the axial groups, 32 *point groups* are produced.

Referring to the lattice, the introduction of symmetry gives rise to a number of lattice groups in which various rational relationships exist between the lattice parameters. One important result of this interaction is the appearance of *centered lattices*, in which the lattice unit cell chosen according to the rules used to set up the 6 crystal systems contains additional lattice points on body or face diagonals. There are 14 such "Bravais lattices." The symmetry groups so far mentioned can in favorable circumstances all be detected from the external morphology of the crystal.

When the combinations of lattice translations and symmetry operations, that is, the symmetry properties of the crystal structure, are analyzed, new symmetry operations are evolved (screw axes and glide planes) and each of the point groups contains many such combinations, adding up to a total of 230 *space groups*. These are detected by diffraction methods. Table 1 summarizes the relations between the crystal systems and the symmetry groups.

CYBERNETICS

Cybernetics can be described as "the science of control in machines and animals," but the connotation of the word (or its equivalent in other languages) shows a difference of emphasis between *control* in the United States and the *handling of information* in continental Europe. For the science of control involves three streams of work: closed-loop feedback systems (sometimes called goal-seeking systems); the manipulation of the information which guides these systems; and processes of filtering to exclude casual disturbances from the information channel as far as possible. The second of these, obviously, and the third, less obviously, can lead on to a consideration of communication, control and thought processes in animals.

One of the earliest applications of closed-loop feedback was to the power steering of ships, and a successor to this application is the power-aided steering of automobiles (see *FEEDBACK*). As soon as the steering wheel is turned, producing a temporary discrepancy between the setting of the steering wheel and the angle of the road wheels, power is applied to the steering linkage in the appropriate direction and maintained until the two agree once more. The qualification "as soon as" is important, because if there were a noticeable delay in response, conditions might have changed so that the position originally demanded would be incorrect by the time it was reached. It can be shown mathematically that the occurrence of delay within the closed loop may cause the system to oscillate about the desired position without coming to rest ("hunting"); moreover, there is always a tendency for the magnitude of the delay round the loop to increase with the amount of

amplification in the loop; and hence a high-gain loop (one designed to provide a large driving power in response to a small input signal) is particularly susceptible to this type of instability. The general principles involved for linear systems have been outlined by Bode,¹ and one of the tasks of the "servo" designer is to ensure by analysis (for which there are several mathematical techniques) that the system is free from this type of instability. In practice, his task is complicated by the effects of nonlinearity and of interference or "noise".

Closed-loop control systems are often designed to respond to signals which may be regarded as a kind of "information." For example, in the push-button controlled elevator the passenger informs the machine of the floor to which he wishes to travel by pushing a button, and the elevator continues in motion until the desired floor is reached; or in the programmed control of machine tools, information may be fed in via punched cards, punched paper tape or magnetic tape. "Information" is then an essential part of cybernetics, and the idea of information as a quantity which can be measured in physical terms dates effectively from Shannon's work on the information-capacity of communication channels.² The essence of Shannon's work, the germ of which lay unperceived in the earlier work of the telegraphists Kelvin, Carson and Nyquist, is that information can be defined as a quantity which is invariant to transformations of the wave forms by which it is conveyed. Such transformations are known as "coding" of information. Shannon showed further that there is a maximum rate (to be achieved by "ideal coding") at which information can be communicated without error through a physical channel of specified bandwidth and signal-to-noise ratio. To be measurable, the information must be finite. If there is a finite group of n different signals of which the i th occurs with probability (or relative frequency) p_i , the quantity

$$I = - \sum_{i=1}^n p_i \log p_i$$

is the information conveyed by the group of signals. There are physical as well as mathematical arguments for stating that information is the negative of ENTROPY, the latter quantity being as defined in STATISTICAL MECHANICS. The term cybernetics is sometimes taken to include the handling of information in Shannon's sense of that word, with emphasis on the use of information in control systems rather than on the communication of information over long distances.

The third line of work in cybernetics is the study of methods of minimizing interference, of separating signals from noise, and the classic work in this field is that of Norbert Wiener. Following his work on generalized Fourier series,³ Wiener showed⁴ the relationship between the autocorrelation function of a random waveform and its power spectrum, the Wiener-Khinchine theorem:

$$W(f) = 2 \int_0^\infty \psi(\tau) \cos 2\pi f\tau \, d\tau$$

where $W(f)$ is the power spectrum (spectrum of squared amplitudes) and $\psi(\tau)$ is the autocorrelation function for lag τ . He also showed how related mathematical techniques could be used to design a filter which for given statistical characteristics of signal and of noise will give an output having least mean square error (the Wiener-Hopf equation). Similar mathematical techniques are widely used to determine the internal characteristics of automatically controlled systems (e.g., chemical process plants) without interrupting their operation: either a small random disturbance is superimposed on the control signals, or naturally occurring disturbances are utilized, and comparison of the signals at the input and output of the system allows its internal characteristics to be evaluated.

From the evaluation of the characteristics of a system one proceeds to their improvement and there is a whole class of *adaptive control systems* whose characteristics are automatically modified in accordance with current conditions. One application is to the adjustment of the filtering characteristics of a control system to suit the types of signal and noise being applied to it at any time. Another application is to the optimization of performance of plant such as chemical process control and distillation plant. In this type of plant the function of automatic control was originally to maintain specified conditions of temperature, pressure, flow, etc.; but in optimizing control, the automatic equipment finds and maintains optimum conditions which it can vary in response to changes in external circumstances such as change in the raw material at the input, and it can be used to find experimentally optimum conditions which are not known in advance.

Adaptive systems are more sophisticated than automatic controls having fixed characteristics, and in addition to their superficial resemblance at least to the instinctive behavior of animals, they have other relationships with biological systems, the two most remarkable characteristics of which are the ability to learn and the ability to transfer functions from one physical channel to another in case of damage. It must first be said that the idea of coding of information has made a decisive contribution to knowledge of the mechanism of the nervous systems of animals. Much is now known about the forms of pulse code by which information is sent along nerve channels, and the neuron of biology is coming to be regarded as the prototype element for performing the operations of Boolean algebra, so that the designer of digital computers uses the neuron symbol to denote schematically an elementary circuit which will be constructed from electronic components. The adaptive control system shows some of the characteristics of learning, and electronic models of the type known as "conditional probability machines"⁵ can be made to exhibit behavior resembling that of conditioned reflexes in animals. Attempts have been made to press the analogy further in two directions. Ross Ashby devised a model which he called the "homeostat" which made a random search to find a stable position

which it could then maintain constant, and the constancy bears some analogy to the homeostasis (constancy) of temperature, chemical constitution of blood stream, etc. in the higher animals. Then various workers, such as W. G. Walter⁶, constructed mechanical toy animals which could apparently exhibit elementary forms of animal behavior such as the search for "food," and of which the more sophisticated versions could learn to thread a simple maze.⁷ The relevance of the behavior of these devices to the mechanisms of animal behavior is debatable. Finally, familiarity with the concept of coding of information makes it easier to understand "the genetic code," i.e., the way in which genetic information can be stored in the pattern of chemical groups along the length of a complex molecule, and in some ways, this is the most spectacular contribution of cybernetics to human knowledge.

CYCLOTRON*

The cyclotron is an accelerator of ions widely used to study the nucleus, to produce radioactive substances, and to study the interactions of ion-

izing radiation with living systems and with inert matter. It is equally important as the first of a class—*Magnetic Resonance Accelerators*—which includes the various kinds of synchrotron (see SYNCHROTRON) as well as synchrocyclotrons and sector focused cyclotrons. The essential feature of this type of accelerator is that acceleration of charged particles to high energies is achieved by a successive application of small accelerations in synchronization with the rotational period of the particles in a magnetic field. The condition for synchronization is simple and can be derived as follows: A charged particle moving perpendicularly to the lines of force in a magnetic field will describe a circle which is defined by the equilibrium between the Lorentz force $F_L = eBv$ and the centrifugal force $F_c = mv^2/r$. Equating these gives the rotational frequency of the particles which is set equal to the frequency of the accelerating field. This is the *Cyclotron Resonance Condition*:

$$f_a = f_0 = \frac{eB}{2\pi m} \quad (1)$$

where

- f_a frequency of accelerating field
- f_0 rotational frequency
- e - charge of ion
- m - mass of ion
- B - magnetic field strength.

The important fact is that the rotational frequency is independent of the energy of the particle and depends only on quantities which are (approximately) constant. In 1929 the possibility of using this relationship as the basis for an accelerator occurred to Ernest O. Lawrence, who like many other physicists at the time had been inspired by Rutherford's success in disintegrating atoms with alpha particles from natural sources to seek a means of producing a controlled beam of high energy particles. The practicability of the idea was demonstrated, and most of the essential features of the Cyclotron were developed by Lawrence, M. Stanley Livingston, N. E. Edlefsen, and others during the next few years.

Figure 1 is a schematic diagram showing the principle components of a cyclotron. The dees are two hollow semicircular electrodes in a vacuum tank located between the poles of an electromagnet which provides an approximately uniform magnetic field over the entire region. The dees are part of an electrical resonant circuit which may be excited by an oscillator whose frequency is adjusted to the rotational frequency given by Eq. (1). Ions are produced by an electric discharge in a source located at the center. They are drawn from the source and accelerated into a dee while it is negative, they follow a semicircular path in the (electrostatic) field free interior of the dee and again arrive at the gap between the dees where, by that time, the voltages are reversed in sign and they are accelerated again. The ions describe semicircles of increasing radius as their

*Effort supported by U.S. Atomic Energy Commission.

FIG. 1

velocity and energy increase as a result of repeated accelerations. When they reach the maximum radius of the dee, they enter a channel between a septum in one of the dees and the deflector. The deflector is charged negatively and draws the particles out where they may strike a target in the target chamber or they may travel some distance as a beam outside the cyclotron before they are used.

The kinetic energy of the accelerated particles is given by:

(2)

where T is the kinetic energy and R is the radius of ion path at point of extraction. For protons, Eq. (1) reduces to $f = 1.52B$ Mc/sec and Eq. (2) to $T = 3.12 \times 10^{-4} B^2 R^2$ MeV with B in kilogauss and R in inches. The usual values of B are from 15 to 22 kilogauss.

In addition to the resonance condition, a successful cyclotron requires that the orbits be stable, i.e., they must remain in the median plane and at the appropriate radius. The first is achieved by introducing in the magnetic field a small negative gradient with respect to radius. The field lines are then bowed as shown in Fig. 2, and the Lorentz force on a particle off the median plane has a

FIG. 2

vertical focusing component. Radial stability results from the fact that the orbit of the particle is an equilibrium orbit with the inward Lorentz force predominating at radii larger than the equilibrium orbit and the centrifugal force predominating at smaller radii. Ions which are displaced either vertically or radially then execute oscillations about the equilibrium orbit. If the magnetic field is described by the index,

$$n = -\frac{r}{B} \frac{\partial B}{\partial r} \quad (3)$$

where r is the radius, then it can be shown that for $0 < n < 1$ stable oscillations occur with frequencies:

$$f_r = f_0 \sqrt{n} \quad (4)$$

$$f_z = f_0 \sqrt{1-n}$$

where f_r is the frequency of vertical oscillations and f_z is the frequency of radial oscillations.

The negative gradient in the magnetic field results, however, in the situation where the rotational frequency, Eq. (1), is not exactly the same at all radii. In addition, it must be noted that the mass in Eq. (1) is the relativistic mass, $m = m_0 / \sqrt{1 - v^2/c^2}$ and increases with energy. The result of these two discrepancies is that the rotational frequency of the ion decreases as it is accelerated and there is an accumulated phase lag between the ion and the accelerating field which when it approaches π radians, results in no further acceleration. The energy limit of the conventional cyclotron can be shown to be proportional to the square root of the accelerating potential and to be about 30 MeV for protons with a dee-to-dee potential of 200 kV. It has not been possible to reach the theoretical maximum energy in practice, and for reasons made clear in the next sections, the incentive to do so has disappeared. The maximum energy which has been attained with protons is 22 MeV and that required about 500 kV on the dees. Currents in cyclotrons are usually of the order of 100 μ A but up to 1 mA has been attained. The most commonly used ions are protons, deuterons, and alpha particles, although heavier ions such as carbon, nitrogen and oxygen ionized to +3 or +4 have also been accelerated.

A possibility of achieving higher energies with cyclotrons was opened up in 1945 when V. Veksler and E. M. McMillan independently pointed out the phase stable characteristic of the cyclotron resonance condition [Eq. (1)] which is apparent if the equation is rewritten in terms of particle energy:

$$f_0 = \frac{Be c^2}{2\pi(E_0 + T)} \quad (5)$$

where E_0 is the rest energy of the particle.

Consider a particle rotating in a cyclotron at the resonant frequency and crossing the accelerating gap at a phase such that it gains no energy and that a later arrival causes it to lose energy. If this

FIG. 3

particle is perturbed by an excess of energy, f_0 decreases and the particle loses energy. If the particle is perturbed in phase so that it arrives at the accelerating gap too early, it gains energy, f_0 decreases, and the phase slips back. Perturbations in energy or phase thus result in oscillations about the equilibrium phase. Under these conditions, if the accelerating frequency of a cyclotron is slowly decreased, the ions will execute stable oscillations about that phase which will give sufficient energy gain so that the radius and energy are matched as the orbits expand. This is the *Principle of Phase Stability* as applied to the Synchrocyclotron. It completely removes the energy limitation of the cyclotron previously discussed. This principle was immediately exploited and synchrocyclotrons (also sometimes called Frequency Modulated or FM Cyclotrons, and in the U.S.S.R., Phasotrons) have been built

which give protons up to 700 MeV. The only limit is the economic one due to the large size of the magnet.

The important structural difference between a synchrocyclotron and a conventional cyclotron is in the provision for a variable frequency. This is accomplished by placing a variable capacitor in the resonant dee circuit. Rotary blade capacitors have been in common use for this purpose, but in more recent designs, vibrating blade capacitors have been preferred. The required frequency swings are about two to one, and the usual modulation frequencies are about 60 to 100 cps. The ions are accelerated in pulses as the accelerating frequency sweeps through its modulation cycle in contrast to the continuous acceleration in a conventional cyclotron. The result is that average currents in synchrocyclotrons are about 1 per cent of cyclotron currents, thus

TABLE I.

removal of the energy limit has been accomplished at the expense of a current limitation.

Another method of circumventing the energy limit of the cyclotron was proposed by Thomas in 1938, seven years before the principle of phase stability was enunciated. In the Thomas proposal, the average magnetic field increases with radius so that the resonance condition may be exactly matched by a constant accelerating frequency as the ion gains energy. The axial focusing force is supplied by an azimuthal variation of the magnetic field which may be obtained by using sector magnet poles, Fig. 3. The ion orbits are then no longer circular, and the radial component of velocity interacting with the azimuthal component of magnetic field produces an axial focusing force. This is the "edge focusing" which occurs when an ion crosses a fringe field obliquely, and it has long been used in mass spectrometers and other devices.

This idea was well in advance of the theory and practice of the cyclotron art at the time and was not immediately exploited. Development beginning in 1949 and extending to recent years has resulted in a whole subclass of cyclotrons characterized by a fixed rotational frequency and focusing forces derived from spatial variation in the magnetic field. For example, if the sectors are spiral shaped as in Fig. 3, additional focusing forces of alternating gradient type are developed. These cyclotrons are variously called Sector Focused, Isochronous, and AVF (azimuthally varying field) cyclotrons. They have energies well beyond the energy limit of the conventional cyclotron and, at the same time, are capable of high average currents because they operate at a constant frequency. Provision of auxiliary magnet coils on the pole tips, to trim the field shape over a range of values of average field, and adjustable frequency oscillators, to provide for different ions and a variation in maximum energy, have made the modern cyclotron of this type very flexible.

Table I gives a comparison of the salient features of examples of each of the three main types of cyclotron.

CYCLOTRON RESONANCE (DIAMAGNETIC RESONANCE)*

The term cyclotron resonance is used to designate the resonant coupling of electromagnetic power into a system of charged particles undergoing periodic orbital motion in a uniform static magnetic field. The frequency of the electric field at resonance is simply related to the orbital frequency of the electron in the magnetic field. The effect has been observed and studied extensively in gases and in solids.

One important application of the cyclotron resonance principle is made in the acceleration of charged particles, as in a cyclotron. In a uniform magnetic field, H , a charged particle of mass, m_e , undergoes orbital motion with an angular velocity

$$\omega_e = \frac{eH}{mc}, \quad (1)$$

in which e is the charge and c the velocity of light. Energy from the electromagnetic fields, i.e., from the alternating electric and magnetic fields, is transferred into kinetic energy of the particle, and the radius of the particle orbit is increased with no change in angular velocity. Particle acceleration takes place *in vacuo* in order to prevent energy transfer to the gas by means of collisions.

In solids, cyclotron resonance has been successfully applied to studies of electronic energy band structure. The perfectly periodic array of atoms in an ideal solid scatters electrons coherently. An electron experiencing such coherent scattering can be described by the same equations of motion as the free electron, except that the free electron mass is replaced by an effective mass, m^* . Incoherent scattering from crystalline imperfections causes electronic collisions which limit the number of completed electron orbits, thus giving rise to a frequency bandwidth for the cyclotron resonance absorption. The observation of cyclotron resonance requires that the charged particle execute about one complete cyclotron orbit without collisions, or $\omega_e \tau \gtrsim 1$, in which the collision time, τ , is the mean time between incoherent scatterings. A long collision time is achieved by using samples of the highest possible purity and lattice perfection and by cooling to very low temperature (usually liquid He temperature, 4°K) to eliminate the thermal motion of the atoms. The condition for cyclotron resonance can also be satisfied by increasing ω_e through the use of high magnetic fields, e.g., 100-kilogauss static fields are currently available which for free electrons results in $\omega_e \approx 1.5 \times 10^{12}$ rad/sec or an electromagnetic wave length of about 1 mm.

Electrons moving in the periodic lattice of a solid occupy energy levels which are specified by the wave vector quantum number, k , or by the crystal momentum, $\hbar k$. Since the number of electrons is very large, the wave vectors assume an

* Support of U.S. Air Force is acknowledged.

almost continuous range of values. A knowledge of the functional form of the dependence of the energy on wave vector is necessary for a complete description of the behavior of electrons in solids. The simplest form of the relation between energy and wave vector valid for energy bands in cubic crystals is

$$E(\mathbf{k}) = \frac{\hbar^2 k^2}{2m^*}. \quad (2)$$

In this case, the constant energy surfaces in wave vector space are spheres, and the cyclotron mass of Eq. (1) is just the effective mass, m^* . For energy extrema located at general points in wave vector space, Eq. (2) becomes

$$E(\mathbf{k}) = \frac{\hbar^2}{2} \left(\frac{k_x^2}{m_x} + \frac{k_y^2}{m_y} + \frac{k_z^2}{m_z} \right) \quad (3)$$

in which the extremal point is taken as the origin, and m_x , m_y , and m_z are three components of an effective mass tensor. This generalization is also necessary in describing the energy bands for crystals with symmetry lower than cubic.

An expression for the cyclotron effective mass which is valid for an electron orbiting on a constant energy surface of energy E for an arbitrary $E(\mathbf{k})$ is

$$m_c(E, k_H) = 2\pi\hbar^2 \left(\frac{\partial A}{\partial E} \right)_{k_H} \quad (4)$$

in which k_H is the wave vector component parallel to the magnetic field, A is the area of the electron orbit in wave vector space, and $(\partial A / \partial E)_{k_H}$ is the derivative of this area with respect to energy evaluated at constant k_H . For spherical or ellipsoidal constant energy surfaces, the cyclotron mass is independent of both energy and k_H , and for these two simple cases, m_c is given, respectively, by $m_c = m^*$, and

$$\left(\frac{1}{m_c} \right)^2 = \frac{\alpha^2}{m_y m_z} + \frac{\beta^2}{m_x m_z} + \frac{\gamma^2}{m_x m_y} \quad (5)$$

in which α , β , γ are the direction cosines of the magnetic field with respect to the axes of the ellipsoidal constant energy surface.

For solids which have relatively low carrier density (e.g., insulators, semiconductors, and semimetals) the electronic states which are important in the transport properties are located near energy band extrema. For nondegenerate extremal points in wave vector space, $E(\mathbf{k})$ can be expanded in a Taylor's expansion. The leading term of such an expansion would be given by Eq. (3). For degenerate points (positions where two or more levels have the same energy), a simple generalization of a Taylor's expansion must be used. In solids with relatively high carrier density (e.g., metals), the transport properties are determined by electronic states which are far from the energy extrema and the $E(\mathbf{k})$ relation is not adequately described by a Taylor's expansion.

Cyclotron resonance experiments have been particularly successful in the quantitative determination of the band parameters of the semiconductors silicon and germanium. The successful application of this technique in these semiconductors is attributed to the high quality of the available material, and to the complete classification of the possible forms of the theoretical band structure model. Since in these materials the intrinsic carrier concentration is extremely small at low temperatures, electrons are optically excited out of filled valence levels in the crystal in order to produce sufficient carriers to obtain a measurable signal. Resonances are observed both for the excited electrons and for the holes left behind in the empty levels in the valence band.

In metals, the high carrier density requires modification of the conventional cyclotron resonance experiment. Two important consequences of this high carrier density are the nonuniform penetration of the electromagnetic field in the skin depth and the inapplicability of the simple effective mass theory to describe the electronic states. To overcome the problem of the small electromagnetic penetration depth, the geometrical arrangement suggested by Azbel and Kaner is used. The static magnetic field is applied in the plane of a flat sample, so that the electrons near the surface can be accelerated by the electromagnetic fields, and the orbits described by a cyclotron radius which is large compared with the skin depth. In this way, whenever the applied frequency is a multiple of the cyclotron frequency, a resonant condition is satisfied. This type of cyclotron resonance experiment yields an effective mass at the Fermi energy given by Eq. (4), which is, in general, dependent on the wave vector component parallel to the magnetic field. The interpretation of these experiments is not simple but when coupled with experiments which measure the shape of the Fermi surface, such as DE HAAS-VAN ALPHEN EXPERIMENTS, a fairly complete determination of the electronic band structure is possible. These techniques have been successfully applied in the study of copper.

Cyclotron resonance in ionic crystals allows the measurement of polaron effects. The POLARON denotes the charge carrier together with its local lattice distortion. Cyclotron resonance observed in AgBr has been interpreted as a polaron orbiting in the applied magnetic field.

D

DE HAAS-VAN ALPHEN EFFECT

In 1930, W. J. de Haas and P. M. van Alphen observed an anomalous behavior in the magnetic susceptibility of a pure bismuth single crystal at very low temperatures. Subsequent studies showed that the susceptibility oscillated with changing magnetic field and was in fact periodic in the reciprocal field. This effect was thought for some years to be peculiar to bismuth; however, in 1947 it was found in zinc and, shortly afterwards, in a number of other metals. The effect has now been observed in most metals (including ferromagnetic elements), as well as intermetallic compounds and ordered alloys. Related magneto-oscillatory behavior is observed in the electrical resistance, Hall effect, specific heat, ultrasonic attenuation and velocity, and the thermoelectric power. While originally thought to be somewhat of a scientific curiosity, the de Haas-van Alphen effect has become one of the most powerful techniques for studying the Fermi surface in metals.

A basis for an understanding of this effect was provided in 1930 by Landau who showed that for a system of free electrons in a magnetic field, the motion of the electrons parallel to the field is classical while the motion perpendicular to the field is quantized. These ideas were shown by Peierls in 1933 to hold for free electrons in a metal (spherical Fermi surface). As a consequence, the free energy F of the system and, hence, the magnetic moment $M = -\partial F / \partial H$ oscillate with magnetic field H . These results were extended by Blackman in 1938 to the case of ellipsoidal energy surfaces, accounting quite well for the experimental results obtained on Bi.

The importance of the de Haas-van Alphen effect as a tool in studying the Fermi surface was perhaps not fully appreciated until Onsager (1952) showed that the frequencies of the oscillations are directly proportional to extremal cross-sectional areas of the Fermi surface perpendicular to the magnetic field. Onsager arrived at this result by applying the Bohr-Sommerfeld quantization condition to the electron orbits normal to the field. If \mathbf{p} is the electronic momentum and if \mathbf{A} is the vector potential, then $\oint \left(\mathbf{p} - \frac{e\mathbf{A}}{c} \right) \cdot d\mathbf{l} = (n + \gamma)h$,

where $\left(\mathbf{p} - \frac{e}{c} \mathbf{A} \right)$ is the canonical momentum, n is an integer, γ is a phase factor and h is Planck's constant. From the Lorentz force equation

$\dot{\mathbf{p}} = \frac{e}{c} (\mathbf{v} \times \mathbf{H})$, it follows that electron paths in momentum space have the same shape as those in real space but changed in scale by a factor $\frac{e}{c} H$ and turned through 90° . We note that $\oint \mathbf{A} \cdot d\mathbf{l} = \int \nabla \times \mathbf{A} \cdot d\mathbf{S} = HS$, where S is the area of the orbit in real space. Furthermore, the area of the orbit in momentum space \mathcal{A}_p is just $\left(\frac{eH}{c} \right)^2$ times the area in real space, so it follows that $\mathcal{A}_p = (n + \gamma) \frac{ehH}{c}$. Since the momentum is related to the wave number k by $p = \hbar k$, the area in k -space is given by $\mathcal{A}_k = (n + \gamma) \frac{2\pi eH}{ch}$.

If one now considers a free electron metal near absolute zero, the surfaces of constant energy ($E \propto k^2$) in k -space will be a quasi-continuous set of spheres up to some maximum size corresponding to the Fermi energy E_F . When a magnetic field is applied in the z direction, these surfaces will degenerate into a discrete set of cylinders, a consequence of the quantization of states in the x - y plane. This is shown schematically in Fig. 1. As indicated above, the cross-sectional area of the n th cylinder will be given by $\mathcal{A}_k(n)$. Each of these permitted states is highly degenerate, but as the field is increased, and the cylinders expand through the Fermi surface, they must give up their electrons to inner cylinders of lower quantum number. For the inner cylinders, this leads to a rather smooth variation in the free energy of the system, but for the outer cylinder, the occupied length decreases very rapidly as the cylinder approaches the extremal cross section of the Fermi surface (\mathcal{A}_0). This rapid depopulation of the n th cylinder at a critical field given by $1/H_n = 2\pi(n + \gamma)e/\hbar c \mathcal{A}_0$ completes an oscillation in the free energy of the system. As the field is increased further, the process is repeated, giving oscillations in the energy and hence the susceptibility

$\chi = -\frac{1}{H} \frac{\partial F}{\partial H}$ which are periodic in $(1/H)$ with period $\Delta(1/H) = 2\pi e/\hbar c \mathcal{A}_0$. The same result occurs for a Fermi surface of more complicated shape, and if the surface consists of several pieces or sections, there will be oscillations related to the extremal cross-sectional area of each section. Observed de Haas-van Alphen periods found in

Fig. 1. Quantized orbits in a free electron metal illustrating the origin of the de Haas-van Alphen effect. The dashed sphere denotes the Fermi level.

different metals range in value from $\approx 10^{-5}$ to $\approx 10^{-9}$ gauss¹ corresponding to Fermi surface cross sections from $\approx 10^{-13}$ to $\approx 10^{-17}$ cm². A study of the de Haas-van Alphen effect frequencies (proportional to \mathcal{A}_0) for various directions of the applied field relative to the crystal axes can thus be of great value in mapping out the geometrical shape of the Fermi surface.

At temperatures above absolute zero, the quantized orbits or energy levels (Landau levels) are not sharp but are "smeared out" over an energy range of $\approx kT$ by electron collisions with lattice vibrations. This results in a rapid decrease in the amplitude of the oscillations with increasing temperature. The effect of electron collisions with impurities results in a further reduction in amplitude. A general requirement for the observation of the effect is that $\omega\tau \geq 1$, where ω is the cyclotron frequency, related to the time for an electron to complete an orbit, and τ is the mean time between collisions. For this reason, experiments are generally carried out at liquid-helium temperatures ($\approx 4.2^\circ\text{K}$) on ultrahigh-purity crystals.

A detailed theoretical treatment of the de Haas-van Alphen effect was carried out by Lifshitz and Kosevich.⁴ The result for the free energy can be expressed as

$$F \propto TH^{3/2} \exp\{-2\pi^2 k(T+x)cm^*/ehH\}$$

$$\cos\left\{ch\mathcal{A}_0/eH \mp \frac{\pi}{4} - \delta\right\}$$

for the case $2\pi^2 k(T+x)cm^*/ehH \gg 1$. Here k is the Boltzmann constant, δ is a phase factor, T is

the absolute temperature, and x is a factor which takes into account the impurity collision broadening and is related to the relaxation time of the electron (or hole). The quantity m^* is the "effective mass" or "cyclotron mass" of the electron (or hole) for the extremal cross section and is related to the curvature of the energy surface. It can be seen from the above expression that by determining the temperature and field dependences of the amplitude of the oscillations, one can find the effective mass m^* and the scattering factor x .

Of the various techniques for observing the de Haas-van Alphen effect, the torsion balance method and the pulsed field method have been most common. In the former, the sample is suspended in a uniform transverse field (usually from 0 to 40 kilogauss) and the torque exerted on the sample is recorded as a function of field strength. This method has the advantages of high sensitivity and accuracy, but it cannot detect oscillations arising from spherical Fermi surface segments. Furthermore, available transverse field intensities place limitations on its use for very high de Haas-van Alphen frequencies (corresponding to large Fermi surface areas). In the pulsed field method, the specimen is situated inside of a balanced coil system which detects the changing magnetization in a varying field. Magnetic fields rising to 100 to 200 kilogauss in times on the order of 10 msec are produced through discharge of a large condenser bank into a copper-wound solenoid. The high fields enable one to study very high de Haas-van Alphen frequencies. In addition, the method detects isotropic surface segments.

Another technique which combines some of the advantages of both of the above methods uses a dc magnet modulated by a sinusoidally varying field with amplitude smaller than the period of the de Haas-van Alphen oscillations. A signal proportional to the de Haas-van Alphen effect is detected by means of a small balanced coil system surrounding the sample as in the pulsed field method. This technique is particularly suited for use with superconducting solenoids which produce extremely large, high-stability fields with low power requirements.

DENSITY AND SPECIFIC GRAVITY

Density is a fundamental property of matter which is a measure of the compactness of its particles. Density is expressed as the ratio of

mass to volume and depends on the composition of the specimen, its homogeneity, temperature, and especially in the case of gases, on pressure. Density is a property used to identify elements, compounds, and mineral specimens. In the case of minerals where homogeneity varies, a range of densities may be cited as typical of samples of the mineral.

Gases. One way to determine the density of a gas is to weigh an evacuated bulb and then weigh it again filled with the gas, both weighings at known temperature and pressure. The bulb must be dry and free from condensed moisture. The weighing must be corrected for the buoyant force of the air on the bulb. If a two-pan balance is used, an evacuated counterpoise bulb of the same volume may be used. On a single-pan balance, the buoyancy of the air must be calculated for accurate work.

The buoyant effect is the basis for a sensitive method of finding the density of a gas. In the Edwards gas density balance^{3,4} a sealed glass cylinder is at one end of a balance beam and a counterweight at the other. This equipment is mounted within a gastight chamber which is attached to a manometer. Gases are introduced into the chamber—first air and then, after complete removal of the air, the gas whose density is to be measured. The pressure exerted to restore the beam to equilibrium is read in each case. The densities of the two gases are inversely proportional to the pressures required to attain equal buoyant force on the beam within the chamber. A relatively large sample of gas is needed for this method.

The Schilling effusion method for determining the density of a gas⁵ involves measuring the time for a given gas sample of given volume and temperature to escape through a known orifice. This time is compared with the time for an equal volume of dry air under the same conditions. The density of the sample is proportional to the square root of the time of escape.

Liquids. The simplest method of finding the density of a liquid at a specified temperature is to float a hydrometer of suitable range in it and to read the value of the density from the graduations on the hydrometer stem. Such testing is used for the electrolyte in automobile and boat storage batteries and for antifreeze fluids in automobile radiators.

More precise measurement can be made with a Westphal balance. A sinker is weighed in air and again while it is suspended in water. It is then weighed while it is suspended in the liquid to be measured. Since the same volume of liquid is displaced by the sinker in both cases, the buoyant forces are proportional to the densities of the liquids.

A pycnometer is a small glass bottle fitted with a ground-glass stopper through which a capillary hole extends lengthwise. When the bottle is filled with liquid at a given temperature and the contents fill the capillary tube completely (or in some cases to a mark), the pycnometer holds the volume marked on it, or it may be calibrated with a liquid

of known density. The pycnometer must first be weighed dry at the specified temperature, and the weighing must be corrected for the buoyancy of the air. The weight of the contents divided by the volume of the pycnometer is the density of the liquid. Other designs of pycnometers are available, many of them refined for special purposes.

Solids. A wide-mouthed pycnometer allows the introduction of a solid whose density is to be measured. In the Russell form, the stopper has a long graduated tube attached to it and a reservoir above that which can be filled with a dense liquid such as mercury. The apparatus is placed upright and the weight of mercury in the tube is measured. The apparatus is inverted so that the mercury runs into the reservoir. A solid of known weight is placed within the pycnometer, the stopper is inserted, and the liquid is permitted to return. The new and higher reading of the mercury in the stem subtracted from the original reading gives the volume of the solid within the pycnometer. Air bubbles must be avoided.

Mixtures of "density liquids" such as methylene iodide (3.325 g/ml) and benzene (0.87901 g/ml) or similar pairs of miscible liquids are made in such proportions that their densities range between the values given. An insoluble solid has the same density as that of the liquid in which it fails to float or sink. The density of the liquid mixture is checked by the pycnometer or other method.

Both methods depend on the principle of Archimedes that a solid immersed in a liquid has a buoyant force exerted on it proportional to the weight of the volume of the displaced liquid. A simple density measurement can be made by weighing an object in air and then in water. The weight in air divided by the loss of weight in water (density 1 g/ml) is the density of the solid. In case a liquid other than water is used, the volume can be found by dividing the loss of weight of the solid by the density of the liquid in which it is immersed, thus extending the usefulness of the method to solids which are soluble in water but which are insoluble in benzene and other liquids.

A density gradient tube consists of two liquids mixed so that the density gradually and regularly increases from top to bottom. A sample is dropped into the tube, and its density is estimated from the position where it rests within the tube.

Specific Gravity. Specific gravity is the ratio between the density of a specimen and the density of a standard material. For liquids and solids, that standard is ordinarily pure water at 4°C (precisely 3.98°C). Mercury has a density of 13.6 g/ml; water has a density of 1.00 g/ml. Their ratio 13.6 to 1.00 or 13.6, is the specific gravity of mercury. Notice that specific gravity has no units of measurement while density requires measurement units. In the English system, densities are 62.4 times as great as those for solids and liquids in the metric system. Water is 1 g/ml in the metric system, but 62.4 lb/ft³ in the English system. Specific gravities come out numerically the same if English units are used

for the density measurements, as they do for metric units.

For gases, hydrogen (0.08988 g/ml at 760 mm of Hg (torr), and 273°K) and air are the standards. If air is the standard (1.29 g/liter at STP), the specific gravity of hydrogen is 0.0656 and that of carbon dioxide is 1.53.

The specific gravity of sulfuric acid of one concentration is expressed as 1.834.²⁰ This means that sulfuric acid at 20°C is 1.834 times as dense as water at 4°C. The density of this acid is 1.834 g/ml at 20°C.

Density measurements are readily made to four significant figures, and with refinements to seven or eight. Density measurements are sufficiently precise to follow the distribution of isotopes in the course of the electrolysis of lithium fluoride.⁹ The per cent of D₂O in H₂O can be found readily by measuring the density of the mixture.

DIAMAGNETISM

Magnetic susceptibility is defined as $\chi_m = M/H$, where M is the magnetic moment per gram (gram susceptibility) or per mole (mole susceptibility) that is induced by an external magnetic field strength H . If $M > 0$, the susceptibility is *paramagnetic*; if $M < 0$, the susceptibility is *diamagnetic*. Whereas most magnetic phenomena, including PARAMAGNETISM, are manifestations of ELECTRON SPIN, diamagnetism reflects electron angular momentum.

If an external field strength H is applied to a conductor so as to change the number of lines of flux that thread through it, there is induced in the conductor an electric current whose associated magnetic field opposes the change (*Faraday's Law of Induction and Lenz's Law*). In most conductors the current I that is thus induced is rapidly dissipated as heat through the I^2R loss, where R is the electrical resistance. These currents are known as *eddy currents*, and they are of great practical interest in ac applications. However, such transients do not influence the dc measurement of χ_m . There are three other classes of electron-momentum change induced by H that are not dissipated: electron currents in SUPERCONDUCTORS, where the resistance is $R = 0$;

currents of atomic dimension induced in atoms or molecules or the atomic "core" electrons of solids; and microscopic conduction-electron helical currents having quantized helical radii.

In a superconductor, switching on of an H induces eddy currents that permanently shield the inside of the conductor from penetration by the magnetic-field lines. Therefore the superconductor is an ideal diamagnet, except for a small skin depth at the surface. If a superconductor is cooled through the normal-conducting \rightleftharpoons superconducting transition temperature in the presence of H and after the eddy currents induced in the normal-conducting state have been dissipated, the field lines are rapidly expelled from the superconductor (*Meissner effect*). This proves that the ideally diamagnetic state is thermodynamically stable.

An external field H superposes on the motion of atomic or molecular electrons (or the atomic core electrons in solids) a common circular motion about H of angular frequency ω_L , $eH/2mc$, where e/m is the electronic charge-to-mass ratio (*Larmor's theorem*). This atomic current produces an atomic moment that is proportional to the square of the distance of a classical electron from the nucleus, $r_i \sim 1\text{\AA}$. Therefore the diamagnetic contribution from electrons localized about an atomic nucleus is

$$\chi_m^{\text{core}} = -(Ne^2/6mc^2) \sum_i r_i^2,$$

where N is the number of atoms per gram (or mole).

In addition to macroscopic eddy currents, conduction electrons tend to move in microscopic helical paths in the presence of an H . The contribution to χ_m from this helical motion is a purely quantum mechanical effect. The radii of the H -induced helical paths are quantized, which leads to a "bunching" of the energy levels within an energy band of conducting states, and at large H , these "bunches" can be resolved. They are known as *Landau levels* because Landau¹ first presented the quantum mechanical theory of conduction-electron diamagnetism, which for single parabolic energy bands gives

$$\chi_m^{\text{cond}} = -\frac{1}{3}\mu_B^2 N(E_F),$$

where μ_B is the *Bohr magneton* and $N(E_F)$ is the density of energy levels at the *Fermi energy* E_F . Since $N(E_F)$ oscillates with H as successive Landau levels pass through E_F , χ_m^{cond} shows oscillations in large H (*DE HAAS-VAN ALPHEN EFFECT*). Transitions between Landau levels, which are split by an energy $\hbar\omega_p = eH/m^*c$, may be induced by an electromagnetic field of angular frequency ω_p . This gives rise to resonance power absorption as ω passes through ω_p (*cyclotron or diamagnetic resonance*). These two effects are used to map out the contours in momentum space of the Fermi energies in metals.

DIELECTRIC THEORY

A dielectric is a material having electrical conductivity low in comparison to that of a metal. It is characterized by its dielectric constant and dielectric loss, both of which are functions of frequency and temperature. The dielectric constant is the ratio of the strength of an electric field in a vacuum to that in the dielectric for the same distribution of charge. It may also be defined and measured as the ratio of the capacitance C of an electrical condenser filled with the dielectric to the capacitance C_0 of the evacuated condenser:

$$\epsilon = C/C_0$$

The increase in the capacitance of the condenser is due to the polarization of the dielectric material by the applied electric field. The terms "specific inductive capacity" or "permittivity" are occasionally used instead of dielectric constant. The constant ϵ appearing in the Coulomb law of force is called the permittivity, but it is also commonly called the dielectric constant. The relative permittivity or dielectric constant is the ratio ϵ/ϵ_0 , where ϵ_0 is the permittivity or dielectric constant of free space. In the mks system of units, the dielectric constant of free space is 8.854×10^{-12} farad/m, while in the esu system the relative and the absolute dielectric constants are the same. The relative dielectric constant, which is dimensionless, is the one commonly used. When variation of the dielectric constant with frequency may occur, the symbol is commonly primed. When a condenser is charged with an alternating current, loss may occur because of dissipation of part of the energy as heat. In vector notation, the angle δ between the vector for the amplitude of the charging current and that for the amplitude of the total current is the loss angle, and the loss tangent, or dissipation factor, is

$$\tan \delta = \frac{\text{Loss current}}{\text{Charging current}} = \frac{\epsilon''}{\epsilon'}$$

where ϵ'' is the loss factor, or dielectric loss, of the dielectric in the condenser and ϵ' is the measured dielectric constant of the material.

At low frequencies of the alternating field, the dielectric loss is normally zero and ϵ' is indistinguishable from the dielectric constant ϵ_{dc} measured with a static field. Debye has shown that

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} = \frac{4\pi N_1}{3} \left(\alpha_0 + \frac{\mu^2}{3kT} \right) \quad (1)$$

where N_1 is the number of molecules or ions per cubic centimeter; α_0 is the molecular or ionic polarizability, i.e., the dipole moment induced per molecule or ion by unit electric field (1 esu = 300 volts/cm); μ is the permanent dipole moment possessed by the molecule; k is the molecular gas constant, 1.38×10^{-16} , and T is the absolute temperature. An electric dipole is a pair of electric charges, equal in size, opposite in sign, and very close together. The dipole moment is the product of one of the two charges by the distance between them.

In Eq. (1) $\mu^2/3kT$ is the average component in the direction of the field of the permanent dipole moment of the molecule. In order that this average contribution should exist, the molecules must be able to rotate into equilibrium with the field. When the frequency of the alternating electric field used in the measurement is so high that dipolar molecules cannot respond to it, the second term on the right of the above equation decreases to zero and we have what may be termed the optical dielectric constant ϵ_∞ , defined by the expression

$$\frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{4\pi N_1}{3} \alpha_0 \quad (2)$$

ϵ_∞ differs from n^2 , the square of the optical refractive index for visible light, only by the small amount due to infrared absorption and to the small dependence of n on frequency, as given by dispersion formulas. It is usually not a bad approximation to use $\epsilon_\infty = n^2$. The general Maxwell relation $\epsilon' = n^2$ holds when ϵ' and n are measured at the same frequency. The Debye equation may be written in the form

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} - \frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{4\pi N_1}{9kT} \mu^2 \quad (3)$$

A much better representation of the dielectric behavior of polar liquids is given by the Onsager equation

$$\frac{\epsilon_{dc} - 1}{\epsilon_{dc} + 2} - \frac{\epsilon_\infty - 1}{\epsilon_\infty + 2} = \frac{3\epsilon_{dc}(\epsilon_\infty + 2)}{(2\epsilon_{dc} + \epsilon_\infty)(\epsilon_{dc} + 2)} \frac{4\pi N_1 \mu^2}{9kT} \quad (4)$$

Anomalous dielectric dispersion occurs when the frequency of the field is so high that the molecules do not have time to attain equilibrium with it. One may then use a complex dielectric constant

$$\epsilon^* = \epsilon' - j\epsilon'' \quad (5)$$

where $j = \sqrt{-1}$. Debye's theory of dielectric behavior gives

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + j\omega\tau} \quad (6)$$

where ω is the angular frequency (2π times the number of cycles per second) and τ is the dielectric relaxation time. Dielectric relaxation is the decay with time of the polarization when the applied field is removed. The relaxation time is the time in which the polarization is reduced to $1/e$ times its value at the instant the field is removed, e being the natural logarithmic base.

Combination of the two equations for the complex dielectric constant and separation of real and imaginary parts gives

$$\epsilon' = \epsilon_\infty + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + \omega^2\tau^2} \quad (7)$$

$$\epsilon'' = \frac{(\epsilon_{dc} - \epsilon_\infty)\omega\tau}{1 + \omega^2\tau^2} \quad (8)$$

These equations require that the dielectric constant decrease from the static to the optical dielectric constant with increasing frequency, while the dielectric loss changes from zero to a maximum value ϵ''_m and back to zero. These changes are the phenomenon of anomalous dielectric dispersion. From the above equations, it follows that

$$\epsilon_m'' = (\epsilon_{dc} - \epsilon_\infty)/2 \quad (9)$$

and that the corresponding values of ω and ϵ' are

$$\omega_m = 1/\tau \quad (10)$$

and

$$\epsilon_m' = (\epsilon_{dc} + \epsilon_\infty)/2 \quad (11)$$

The symmetrical loss-frequency curve predicted by this simple theory is commonly observed for simple substances, but its maximum is usually lower and broader because of the existence of more than one relaxation time. Various functions have been proposed to represent the distribution of relaxation times. A convenient representation of dielectric behavior is obtained, according to the method of Cole and Cole, by writing the complex dielectric constant as

$$\epsilon^* = \epsilon' + \frac{\epsilon_{dc} - \epsilon_\infty}{1 + (j\omega\tau_0)^{1-\alpha}} \quad (12)$$

where τ_0 is the most probable relaxation time and α is an empirical constant with a value between 0 and 1, usually less than 0.2. When the values of ϵ'' are plotted as ordinates against those of ϵ' as abscissas, a semicircular arc is obtained intersecting the abscissa axis at $\epsilon' = \epsilon_\infty$ and $\epsilon' = \epsilon_{dc}$. The center of the circle of which this arc is a part lies below the abscissa axis, and the diameter of the circle drawn through the center from the intersection at ϵ_∞ makes an angle $\alpha\pi/2$ with the abscissa axis. When α is zero, the diameter lies in the abscissa axis, there is but one relaxation time, and the behavior of the material conforms to the simple Debye theory. When, as may arise from intramolecular rotation, a substance has more than one relaxation mechanism, or, when the material is a mixture, the observed loss-frequency curve is the resultant of two or more different curves and, therefore, departs from the simple Debye or Cole-Cole curve.

If the dielectric material is not a perfect dielectric, and has a specific dc conductance k' (ohms⁻¹cm⁻¹), there is an additional "dielectric loss

$$\epsilon_{dc}'' = \frac{3.6 \times 10^{12} \pi k'}{\omega} \quad (13)$$

The effective specific conductance is given by

$$k' = \frac{1}{4\pi} \frac{(\epsilon_{dc} - \epsilon_\infty)\omega^2\tau}{1 + \omega^2\tau^2} \quad (14)$$

It is evident from this equation that k' increases with ω , approaching a limiting value, k_∞ , the infinite-frequency conductivity, which is attained

when 1 can be neglected in comparison with $\omega^2\tau^2$, so that

$$k_\infty = \frac{\epsilon_{dc} - \epsilon_\infty}{4\pi\tau} \quad (15)$$

In a heterogeneous material, interfacial polarization may arise from the accumulation of charge at the interfaces between phases. This occurs only when two phases differ considerably from each other in dielectric constant and conductivity. It is usually observed only at very low frequencies, but, if one phase has a much higher conductivity than the other, the effect may increase the measured dielectric constant and loss at frequencies as high as those of the radio region. This so-called Maxwell-Wagner effect depends on the form and distribution of the phases as well as upon their real dielectric constants and conductances. Each type of form and distribution requires special treatment. For a commercial rubber, for example, the observed loss may be

$$\epsilon''(\text{observed}) = \epsilon_{dc}'' + \epsilon''(\text{Maxwell-Wagner}) + \epsilon''(\text{Debye}) \quad (16)$$

DIFFRACTION BY MATTER AND DIFFRACTION GRATINGS

According to the principle of Huygens (1629–1695) each point in the space which is touched by a wave gives rise to a spherical secondary wave, which again produces tertiary waves, and so on. Every wave interferes with the next one and quite generally gives rise to diffraction phenomena (see OPTICS, PHYSICAL). Such phenomena in the case of visible light first were observed by F. M. Grimaldi (1618–1663) and mathematically explained by J. Fresnel (1788–1827). G. R. Kirchhoff (1824–1887) gave the first exact mathematical solution of the scalar wave differential equation in terms of a boundary integral. If both the primary and the diffracted rays are parallel (e.g., small source, large distances between diffracting sample and source and detector), we have the experimental conditions of Fraunhofer (1787–1826). With two lenses L_1 and L_2 , a collimator pinhole P in the focal plane of L_1 , and a photographic plate F in the focal plane of L_2 , this condition is fulfilled even for short distances (Fig. 1). Monochromatic light is produced by a Hg lamp with

FIG. 1. Equipment for Fraunhofer diffraction.

a Schott filter *S* and an aqueous solution of CuSO4. If *s*₀ and *s* are unit vectors in the direction of the primary and the diffracted beam, and *λ* is the wavelength of the source, then the diffracted intensity *I* is proportional to

$I(\mathbf{b}) \cong f_e^2 f_\theta^2 |R|^2; R(\mathbf{b}) = F(\rho)$ (1)

where

$\mathbf{b} = \frac{\mathbf{s} - \mathbf{s}_0}{\lambda}$ (2)

and

$F = \int e^{-i\pi(\mathbf{b}\cdot\mathbf{x})} dV_x$ (3)

is the symbol of the Fourier transform. *x* is a vector in physical space, *ρ*²(*x*) is the transparency of the object *M* at the end point of the vector *x*, which lies in the plane of the object, *dv_x* is a surface element of the object, *f*_θ² and *f*_{*e*}² are explained in Table 1 and Eq. (2) below Table 1. Figure 2(a) shows an object *ρ*(*x*) in the form of a parallelogram with the edge vectors *L*₁ and *L*₂, and Fig. 2(b) give its Fraunhofer pattern:

$|R|^2 = |S|^2;$

$S(\mathbf{b}) = |\mathbf{L}_1 / \mathbf{L}_2| \frac{\sin \pi(\mathbf{b}\mathbf{L}_1)}{\pi(\mathbf{b}\mathbf{L}_1)} \cdot \frac{\sin \pi(\mathbf{b}\mathbf{L}_2)}{\pi(\mathbf{b}\mathbf{L}_2)}$ (4)

Fraunhofer used assemblies of *N* parallel oriented metal wires with an intermediate distance *d* and the distance *a* (from center to center), in the direction *s*₁. Hence

$\rho(x_1) = \begin{cases} 1 & \text{for } na - \frac{d}{2} \leq x_1 \leq na + \frac{d}{2} \\ 0 & \text{for all other } x_1 \end{cases}$ (5)

TABLE 1. FACTORS *f_e*² AND *f_θ*² FOR DIFFERENT RADIATIONS

		<i>f_e</i> ²	<i>f_θ</i> ²	
1	Visible light	1/λ ²	$\frac{1 + \cos^2 2\theta}{2}$	2θ scattering angle
2	X-rays	$\left(\frac{e^2}{m_0 c^2}\right)^2$	$\frac{1 + \cos^2 2\theta}{2}$	<i>e</i> electric charge of an electron <i>m</i> ₀ rest mass of an electron
3	Electrons	$\frac{m_0 e^2 \lambda^2}{2h^2}$	1/sin ⁴ θ	<i>c</i> velocity of light <i>h</i> Planck's constant
4	Neutrons	Cross section	Polarization factor	λ (de Broglie) wave length

FIG. 2. (a) Parallelogram as diaphragm. (b) Fraunhofer pattern. Secondary maxima of the shape factor *S*² (Eq. (4)).

FIG. 3. (a) Steel balls in a crystalline lattice. (b) Bragg reflections with shape factor S^2 .

and

$$I(b_1) = \frac{1}{a} f^2 Z |S|^2 \quad (6)$$

$$f = \frac{\sin \pi b_1 d}{\pi b_1}; \quad Z = \frac{1}{a} \sum_n P(b_1 - n/a);$$

$$S = \frac{\sin \pi b_1 Na}{\pi b_1} \quad (7)$$

f is the Fourier transform of a single slit, S that of the shape of the whole lattice (length Na). Z is the "reciprocal" lattice point function (lattice factor) of the centers of the wire, since $P(b_1 - 0)$ is a normalized point function at $b_1 = 0$. The symbol of convolution \sim is defined for both functions $G_1(\mathbf{b})$ and $G_2(\mathbf{b})$ in Fourier space, and $g_1(\mathbf{x})$ and $g_2(\mathbf{x})$ in physical space by

$$\widehat{G_1(\mathbf{b})G_2(\mathbf{b})} = \int G_1(\mathbf{c})G_2(\mathbf{b} - \mathbf{c})d\mathbf{v}_c \quad (8)$$

$$\widehat{g_1(\mathbf{x})g_2(\mathbf{x})} = \int g_1(\mathbf{y})g_2(\mathbf{x} - \mathbf{y})d\mathbf{v}_y \quad (9)$$

In the one-dimensional case of Eq. (6) c is to be replaced by the scalar quantity c_1 and $d\mathbf{v}_c$ by dc_1 . Two-dimensional gratings are of high interest, since their Fraunhofer pattern gives all the information we need to understand the more complicated structural theories of three-dimensional matter. This will be shown below.

The technique of preparing such models is quite easy: In the examples of Figs. 4, 5, 6, 7, 8, 10 and 12, the objects were painted with india ink on paper 15×15 inches and then photographed on fine-grained films 0.5×0.5 inch with steep gradation characteristics (for instance Peruline film F 10). The black ink points now become transparent on a black background. In the models of Figs. 3, 9 and 11, steel balls of 2 to 3 mm diameter were placed into the focal plane of a lens system and photographed with a linear reduction 1:15 on the same film material mentioned above.

By defocusing the system, one obtains diaphragms, where the single balls do not touch each other (Figs. 3 and 9, but not Fig. 11). This is quite advantageous, since the width of the atom-factor f^2 [see Eq. (6)] is larger and more reflections are visible.

Fig. 3(a) shows a model of a two-dimensional ideal periodic "point lattice," and Fig. 3(b) represents its Fourier transform.

$$\rho(\mathbf{x}) = \sum_r P(\mathbf{x} - \mathbf{x}_r); \quad \mathbf{x}_r = p_1 \mathbf{a}_1 + p_2 \mathbf{a}_2 \quad (10)$$

$$R^2 \sim Z(\mathbf{b}) = \frac{1}{|\mathbf{a}_1 \wedge \mathbf{a}_2|} \sum_h P(\mathbf{b} - \mathbf{b}_h); \quad \mathbf{b}_h = h_1 \mathbf{A}_1 + h_2 \mathbf{A}_2 \quad (11)$$

where \mathbf{a}_1 and \mathbf{a}_2 are the vectors of a lattice cell of the model, and \mathbf{A}_1 and \mathbf{A}_2 are those of the "reciprocal" lattice cell (in \mathbf{b} -space)

$$\mathbf{A}_1 = \frac{\mathbf{a}_2 \wedge \mathbf{a}_3}{\mathbf{a}_1(\mathbf{a}_2 \wedge \mathbf{a}_3)}; \quad \mathbf{A}_2 = \frac{\mathbf{a}_3 \wedge \mathbf{a}_1}{\mathbf{a}_2(\mathbf{a}_3 \wedge \mathbf{a}_1)} \quad (12)$$

\mathbf{a}_3 is an arbitrary vector orthogonal to \mathbf{a}_1 and \mathbf{a}_2 , and p_1, p_2, h_1 and h_2 are integers. Since the lattice of Fig. 3(a) is bounded if one multiplies $\rho(\mathbf{x})$ by the shape function $s(\mathbf{x})$ of the lattice (which is 1 inside the lattice, and zero out of it) the p -summation can be extended to infinity. From the convolution theorem one obtains generally

$$Fg_1g_2 = \widehat{G_1G_2}; \quad F\widehat{g_1g_2} = G_1G_2 \quad (13)$$

Hence the Fourier transform of the bounded lattice $\rho(\mathbf{x}) \cdot s(\mathbf{x})$ is given again by the convolution product of Eq. (6), where $S(\mathbf{b})$ is the Fourier transform of $s(\mathbf{x})$ and $Z(\mathbf{b})$ is the Fourier transform of Eq. (11). $f^2 = 1$ applies only for "point-like" atoms, otherwise f is the Fourier transform of the shape of each "point."

(a)

(b)

FIG. 4. (a) Linear thermal oscillations without correlations. (b) Debye factor and thermodiffuse background.

M. v. Laue in 1911 prepared an article "Wellenoptik" for the "Encyclopedie der Math. Wissenschaften" and found that Eq. (11) can be easily developed to the Fourier transform of three-dimensional point lattice, where \mathbf{a}_3 is a third lattice vector, non-coplanar to \mathbf{a}_1 and \mathbf{a}_2 . Then \mathbf{b}_h in Eq. (11) must be replaced by

$$\mathbf{b}_h = h_1\mathbf{a}_1 + h_2\mathbf{a}_2 + h_3\mathbf{a}_3; \mathbf{a}_3 = \frac{\mathbf{a}_1 \wedge \mathbf{a}_2}{\mathbf{a}_3(\mathbf{a}_1 \wedge \mathbf{a}_2)} \quad (14)$$

Together with W. Friedrich and P. Knipping using x-rays of a wavelength of the same order of magnitude as that of the atomic distances, M. v. Laue (1912) found three-dimensional diffraction effects in single crystals. $f(\mathbf{b})$ then is the atom form amplitude

$$f(\mathbf{b}) = F(\rho_0) \quad (15)$$

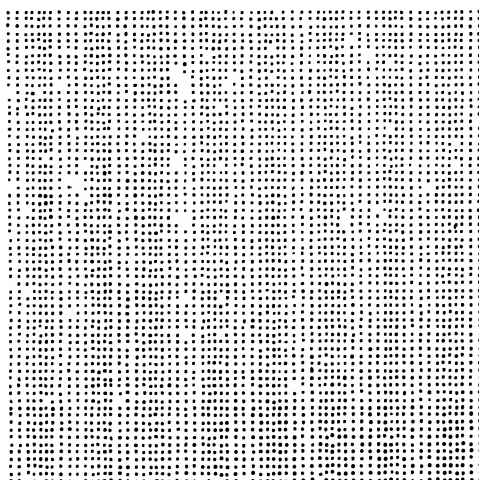

where $\rho_0(\mathbf{x})$ is the electron density distribution of one atom, whose center lies at $\mathbf{x} = 0$.

C. J. Davisson and L. H. Germer (1927) observed the same diffraction phenomena using

electron beams. $\rho(\mathbf{x})$ must then be understood as density distribution of both the electrons (negative) and protons (positive). If single diffraction processes occur, Eq. (6) remains unchanged.

D. P. Mitchell, P. N. Powers, H. v. Halban and P. Preiswerk (1936) found the same diffraction phenomena using thermal neutrons. In this case $\rho(\mathbf{x})$ is the density distribution of the nuclei, each one weighted by the mean of the square root of its respective cross section. The proportional factors f_e^2 , f_n^2 of Eq. (1) for the different radiations are given in Table 1.

The vector \mathbf{b} defined by the integral of Eq. (3) expands the three-dimensional Fourier space and

(a)

(b)

FIG. 5. (a) A single longitudinal wave. (b) Extra Laue spots.

(a)

(b)

FIG. 6 (a) A single transversal wave. (b) Extra Laue spots.

is connected with the unit vectors s , s_0 of the diffracted and primary beam by Eq. (2). This is the construction of Ewald (1914). For a fixed λ and s_0 all values $R(b)$ are in reflection position, which lie on a sphere with radius $1/\lambda$ and the center at $b_0 = s_0/\lambda$.

P. Debye (1915) found that the molecules in the gaseous state give rise to diffraction patterns depending on the structure of the single molecules, without any intermolecular interferences.

In 1927, F. Zernike and I. A. Prins discussed quantitatively diffraction phenomena of liquids and laid down the fundamentals of the structure analysis of amorphous matter. Moreover, P. Debye (1913) and I. Waller (1927) found that real crystals never have a periodic lattice similar to that of Fig. 3(a), since the atoms show thermal

oscillations around their ideal positions. All these different phenomena can be studied quite easily with the help of two-dimensional statistical models and their Fraunhofer patterns, since Eq. (1) holds for all diffraction phenomena. In Fig. 4(a) we have the "frozen" structure of a point lattice with thermal oscillations. They are quite anisotropic and occur only in the horizontal direction. If $H(x)$ is the frequency of the center of an atom being at the distance x from its ideal position and if the atoms oscillate independently from each other, then R^2 is given by

$$R^2(b) = Nf^2(1 - D^2) + \frac{1}{v_r} f^2 D^2 Z |S|^2; \quad D(b) = F(H) \quad (16)$$

(a)

(c)

(b)

FIG. 8. (a) Monoparacrystal with linear horizontal coordination statistics. (b) Its Fraunhofer pattern. The reflections (o , h_2) are crystalline, all others are more or less diffuse (c) Small-angle x-ray pattern from β -feather-keratin (Bear-Rugo, 1951).

(v_r = volume of a lattice cell). In Fig. 4(b) can be clearly recognized the first term of Eq. (16) as a diffuse background. It has a structure in the horizontal direction. The "Bragg reflections" are weakened by the "Debye-Waller factor" D^2 , the more, the stronger is the diffuse background ($1 - D^2$). In nature there exist correlations between the different oscillations and "elastic waves" with an "acoustical" and "optical" frequency creep through the lattice.

Fig. 4(a) gives a single undamped longitudinal and sinusoidal wave with a horizontal wave vector b_x and a wavelength λ_x and amplitude a_x

$$\lambda_x = \frac{1}{|b_x|} = 8a_x; |a_x| = \frac{1}{4}a \quad (17)$$

According to the theories of M. v. Laue (1927) and Laval (1941) in Fig. 5(b) at the reciprocal lattice points

$$\mathbf{b} = \mathbf{b}_h + m\mathbf{b}_x \quad (18)$$

"Extra Laue spots" ("Laval spots") occur. According to conventional theories, $m=1$ is called one-phonon scattering, $m=2$ is two-phonon scattering and so on; and it is said that the frequency ν_0 of the incident radiation is changed into $\nu_0 + m\nu_x$ ("inelastic scattering", ν_x -frequency of the phonons).

In Fig. 6(a) we have again a horizontal wave with the same wave vector [Eq. (17)], which now is transverse. From Laue's theory it follows, that the intensity of a Laue spot of the m th order is proportional to the square of the Bessel function

$$I_m(2\pi(\mathbf{b}\mathbf{a}_x))$$

where m is the order of the Bessel function and \mathbf{a}_x is the amplitude vector of the elastic wave. Hence in Fig. 6(b), strong Laval spots occur only in the vertical \mathbf{b}_h direction; in Fig. 5(b), in the horizontal \mathbf{b}_h direction. Since $I_1(I_2)$ has its maximum at $\mathbf{b}\mathbf{a}_x = 0.25$ (0.5), in Figs. 5(b) and 6(b), the Laval spot $m=1$ at the reflection h_1 ,

(a)

(b)

FIG. 9. (a) Mixed single paracrystal (steel balls). (b) Intensity function (Eq. (6) and (19)).

$h_2 = 1.0$ (0.1) is much stronger and in the 2.0 (0.2) reflection, much weaker, than the Laval spot $m = 2$.

In nature, one never finds such sharp Laval spots, but a completely smooth "thermodiffuse" scattering, and it is said that a "white" spectrum of undamped elastic waves exists.

In Fig. 7(a) strongly damped transverse waves according to Eq. (17) consisting only of two maxima and minima are introduced. Now in Fig. 7(b) quite diffuse spots appear. Hence, in nature, such damped waves could also occur, and if they had a spectral distribution, they could give rise to the same observable thermodiffuse scattering. According to Debye's theory of heat capacity, every wave has a different amplitude a_i , following a Boltzmann statistic. Then in certain regions of a single crystal, the atoms oscillate statistically with different amplitudes than in others. As a result, the lattice cells exhibit different sizes and paracrystalline distortions occur.

Close to the melting point, the amplitudes a_i of the elastic waves become so large that the electron clouds of the atoms suffer large deformations, which damp these waves more and more.

(a)

(b)

FIG. 10. (a) Mixed single crystal with "cooperative forces". (b) Background with diffuse walls (*Nahordnung*).

(a)

(b)

FIG. 11. (a) Polymicroparacrystalline assembly of steel balls. (b) Intensity function of "amorphous" matter.

Another physical reason for paracrystalline distortions below the melting point exists if the "motives" in the single lattice cells have different shapes. Such phenomena have been observed in the "macrolattices" of natural and synthetic high polymers.

Figure 8(a) shows a paracrystalline model, where both coordination statistics H_k are horizontal line functions. Figure 8(b) represents its Fraunhofer pattern and Fig. 8(c) the x-ray small-angle pattern of the β -keratin of the quill of a sea gull (Bear and Rugo (1951)). The cell edge a_2 in the vertical direction parallel to the fiber axis has a constant length of 185Å but statistically

(a)

(b)

FIG. 12. (a) Zirconium crystal with discrete electrons. (b) Rayleigh scattering of the electrons.

changes its direction (with respect to the macroscopic fiber axis) within $\pm 5^\circ$, while the orthogonal edge length a_1 has an average value of 34\AA and changes its length statistically within $\pm 2.5\text{\AA}$. As a result of the van der Waals forces, which allow a variation of the length a_1 orthogonal to the fiber axis, the homopolar forces along a_2 have freedom to change their direction of the molecular chain, within one paracrystal. This paracrystal itself, therefore, shows a flexible character in atomic dimensions.

Equation (6) holds again, if one replaces the crystalline lattice factor Z of Eqs. (7) and (11) by the paracrystalline lattice factor

$$Z(b) = \frac{1}{v} \prod_{k=1}^3 \text{Re} \frac{1 + F_k(b)}{1 - F_k(b)} \quad (19)$$

$$F_k(b) = F(H_k) \quad (20)$$

H_k is a so-called coordination statistic. $H_k(\mathbf{x})$ is the "a priori" probability of finding a cell edge vector $\mathbf{a}_k = \mathbf{x}$ in a certain paracrystalline lattice cell.

For the same reason, in mixed crystals consisting of atoms of different sizes, paracrystalline distortions can also occur.

Figure 3(a) showed a model of steel balls of the same size, building up a crystalline lattice. Figure 3(b) represents its Fourier transform. In Fig. 9(a) steel balls of different sizes built up a paracrystalline lattice, whose Fraunhofer pattern [Fig. 9(b)] exhibits characteristic features of a paracrystalline lattice [cf. Fig. 8(b)].

In Fig. 10(a) another model of a mixed crystal is given without paracrystalline lattice distortions. Now the two kinds of atoms are not distributed totally randomly to the lattice points. Hence the Fraunhofer pattern of Fig. 10(b) shows a diffuse background, which is not given by

$$N(f^2 - f^2) \quad (21)$$

and which presents "diffuse walls" in the vertical direction at $h_1 = \pm \frac{1}{2}$ of a width $\delta h_1 \sim \lambda/4$. This means that in the horizontal direction, rows of about 8 atoms show a kind of "superstructure" (*Nahordnung*, "cooperative order"). This "superstructure" has a psychological background: The technician, painting the models row by row in the horizontal direction was anxious to choose thick and thin atoms quite arbitrarily. However, he did not use a Monte Carlo Method, but tried as arbitrarily as possible to draw statistical sequences. Unfortunately, after he painted a thick atom he tended to choose a thin one, etc. Unconsciously, he introduced "cooperative forces."

Similar diffuse walls are observed in ferroelectric NaNO_2 above the Curie point: In this case, rows of about six NaNO_2 molecules have parallel oriented polar axes, and have built up microferroelectric domains in a statistically paraelectric matrix (M. Canut and R. Hosemann, 1964).

In Fig. 11(a), similar to Fig. 9(a), steel balls of different sizes which now built up a structure of

single small paracrystallites were used. The Fraunhofer pattern, Fig. 11(b), shows the typical features of a liquid or melt or "amorphous" solid. Hosemann and Lemm (1964) have proved, that in molten gold and lead such paracrystals can be found with average diameters of 12\AA to 40\AA .

After having completed the step from crystals to amorphous matter, Fig. 12(a) gives an example of a special gas and Fig. 12(b) at larger b -values, the gas-interferences. Lord Rayleigh (1842-1919) proved that here phase relations between the single scattering centers are destroyed in the average as a consequence of their irregular positions. Since in Fig. 12 only 5200 centers were used, "ghosts" remain in the Fraunhofer pattern. Besides this fluctuation the intensity at large b -values is given by the shape of the single points. Moreover in Fig. 12(a) every 40 points cluster together. The clusters are arranged in a crystalline lattice. Hence, at small angles in Fig. 12(b), "Bragg-reflections" whose intensity is proportional to the squared transform Eq. (15) do occur. ρ_0 is now a forty-point function different for each cluster, and in Eq. (6), f must be replaced by the average \bar{f} . The diffuse background of Fig. 12(b), which now is the statistical fluctuation of the density distribution ρ_0 is given again by Eq. (21). If we replace the word "cluster" by zircon atom and "point" by electron, Fig. 12(a) gives an instantaneous picture of the electron configuration in a zirconium crystal. The Bragg reflections give in this case information about Schrodinger's wave functions for electrons

$$\overline{\rho_0(\mathbf{x})} = \psi\psi^*$$

and the fluctuation term of Eq. (21) gives some information about the structure of a single electron. In reality, Compton processes disturb the diffraction. There is some hope for further detailed studies.

DIFFUSION IN LIQUIDS

Diffusion, in a macroscopic sense, is a universal process that leads to the elimination of concentration gradients in gases, solids, or liquids. At the molecular level, it arises because atoms or molecules undergo small, essentially random displacive movements as a result of their thermal energy. Such motions of individual particles may be likened to a kind of aimless three-dimensional *random walk*. If we limit our attention to the displacement of a single particle in a given direction from its position at some arbitrary zero of time, the *probability* that it will be found at a distance, $\pm x$, from its origin after a time, t , is given by:

$$P(x, t) = \frac{1}{2(\pi Dt)^{1/2}} \exp(-x^2/4Dt) \quad (1)$$

In this equation, the parameter D , called the *diffusion coefficient*, is a measure of the average rate with which the displacement of the particle occurs.

If, instead of attempting to follow the random motion of an individual particle, we introduce a large number of particles C_0 at a point within the system, their concentration $C(x, t)$ will vary with time and distance in a given direction according to:

$$C(x, t) = \frac{C_0}{2(\pi Dt)^{1/2}} \exp(-x^2/4Dt) \quad (2)$$

Both equations have the form of the well-known Gaussian error curve, which gives the distribution of random errors to be expected in a large set of measurements. Figure 1 illustrates these equations,

FIG. 1. Concentration or probability profiles for one-dimensional diffusion for times t_1 and t_2 .

showing the probability of finding a single particle at a distance from its origin (or the concentration distribution of a finite quantity of a substance) after times, t_1 and t_2 .

Equation (2) is a particular solution of a pair of more general differential equations known as Fick's laws. Consider a plane of unit cross-sectional area in a system, across which a concentration gradient, $\partial C/\partial x$, exists. There will be a net flux of matter, J_x , through the plane from the region of higher to lower concentration given by Fick's first law:

$$J_x = -D \frac{\partial C}{\partial x} \quad (3)$$

In principle, it is possible to determine the coefficient of diffusion on the basis of Eq. (3) by measuring the net quantity of matter that crosses through unit area of the plane in unit time. This proves to be difficult in liquids or solids, however, and an additional complication is that the concentration gradient $\partial C/\partial x$ is not constant but decreases with time.

For this reason, it is more feasible to measure the accumulation of matter in a small volume element after a measured period of time. We may consider such a volume element to be bounded by parallel planes of unit area, separated from one another by a distance dx , as shown in Fig. 2. The

rate of change of concentration within the volume element is expressed by Fick's second law:

$$\frac{1}{dx} \left[J_x - \left(J_x + \frac{\partial J}{\partial x} \cdot dx \right) \right] = \frac{dC}{dt} = D \frac{\partial^2 C}{\partial x^2} \quad (4)$$

This is the fundamental equation, upon which all experimental studies of diffusion depend.

One of the most widely used of the absolute methods for measuring diffusion coefficients of liquids is the "open capillary" technique, devised by Anderson and Saddington.¹ A capillary tube, usually less than 1 mm in diameter and 2-3 cm in length, is filled with an isotopically labeled substance and immersed in a thermostatted bath of the unlabeled liquid. Interdiffusion of the labeled and unlabeled molecules occurs across the open end of the capillary, and at the end of the experiment, the average concentration of labeled substance remaining in the capillary is determined by suitable radiochemical or mass spectrometric techniques. The relation between the diffusion coefficient and the initial and final concentration of labeled substance in the capillary is given by a series solution of Fick's second law:

$$\frac{C_{av}}{C_0} = \frac{8}{(\pi)^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left[-(2n+1)^2 \pi^2 Dt/L^2\right] \quad (5)$$

In this equation, for which L and t are, respectively, the capillary length and time, the series converges rapidly and as a rule may be terminated after the first and second term with negligible error.

FIG. 2. Diffusive flux across parallel planes.

A completely different method for the measurement of diffusion coefficients in the liquid state is based upon nuclear magnetic resonance (NMR). An assembly of atomic nuclei which have been excited to some nonequilibrium spin distribution will return to thermal equilibrium by a mechanism that involves the coupling of the nuclear spins with their local molecular environment. The rate of the return to equilibrium is characterized by a *relaxation time* (T_1 , the spin-lattice relaxation time), and is governed by the variations in the local magnetic field at nuclei which are induced by the translational motions of neighboring molecules. Bloembergen, Purcell, and Pound² developed the basic theory which relates the spin-lattice

relaxation time to the diffusion coefficient of molecules, and made the first measurements on water and a series of hydrocarbons to test its validity.

Studies of the temperature dependence of the diffusion coefficient of liquids generally lead to an empirical relationship of the form:

$$D = D_0 \exp(-Q/RT) \quad (6)$$

where D_0 and Q are experimental parameters that are essentially temperature-independent and characterize the diffusion process in the system at hand. Because of the exponential form of Eq. (6), the mechanism of diffusion in liquids is often assumed to be an activated process, by analogy with other kinetic processes to which the *absolute reaction rate theory*³ has been applied with much success. According to this theory, the rate-limiting step of a kinetic process is determined by the frequency with which atoms or molecules acquire sufficient energy through thermal fluctuations to surmount an energy barrier identified by the parameter Q . It has not yet proved possible to make accurate *a priori* calculations of D_0 and Q on the basis of the activated state theory, however, and the exponential form of Eq. (6) is no proof that the mechanism of atom transport in liquids is a thermally activated process in any simple sense. At this time, it appears that a more fundamental insight into the structure and dynamic interactions of molecules in the liquid state will emerge from theories⁴ which concern themselves with the cooperative motions of particles that exchange momenta with one another during collisions. The success of such efforts will depend upon more accurate knowledge of intermolecular potentials.

The range over which diffusion coefficients of liquids⁵ vary is much more limited than that of solids (see DIFFUSION IN SOLIDS). As a rule, experimental values lie between 10^{-4} and 10^{-6} cm²/sec, but despite this relatively narrow compass, they contain information that must lead to a more complete description of the disordered liquid state.

DIFFUSION IN SOLIDS

The term "diffusion" refers to the random motion, generally activated by local fluctuations of thermal energy, of particles through a medium. The particles with which we shall be concerned are atoms and molecules; the medium can be various types of solids. Of special interest will be crystalline solids—these include all metals, most ionic substances, and many covalent ones—in which the atoms occupy periodic and well-defined sites.

The migrating particles may themselves be uniformly distributed constituents of the host solid; this is called self-diffusion. When the diffusing system contains chemical inhomogeneities or when a foreign substance diffuses in from the surface, we speak of chemical or of impurity diffusion. Diffusion processes are technologically important in the oxidation and tarnishing of metals, where one reactant must migrate through the layer of reaction product, and in the annealing of deformed or radiation-damaged materials. Self-diffusion is an essential step in the photographic process in silver halides, and impurity diffusion is widely used in the fabrication of semiconductor devices such as transistors. Many metals, such as steel and duralumin, are hardened by solid-state precipitation and reaction, in which diffusion plays a dominant role. It is also significant in the powder metallurgy technique of fabrication of parts from high-melting metals.

If, in the medium, there are variations in the concentration of the migrating atoms—perhaps chemically different atoms or, in the case of self-diffusion, radioactive tracer isotopes—then there occurs a net drift of the diffusing species from regions of high concentration to those of lower concentration. This flow takes place even though each individual atom may migrate completely at random. It is a statistical result of the fact that if there are more atoms per unit volume of, say, A to the left of a given plane than to the right, then even with random, nondirected motion, more A atoms will cross the plane from the left than from the right. We can define the flux of A as the net excess of A atoms crossing a plane of unit area in unit time. Experimentally, this flux is found to depend on the chemical natures of the medium and the diffusing species. If the medium is isotropic or is a crystal of cubic symmetry, the flux is along the direction of the concentration gradient. Moreover, if the system is not too thermodynamically nonideal, the flux is proportional to the concentration gradient; the constant of proportionality is called the diffusion coefficient, D . Thus, we write the flux $J = -D dc/dx$, where the negative sign indicates that the net flow is toward the region of lower concentration. This statement is known as Fick's law. If lengths are measured in centimeters and time in seconds, D is in units of square centimeters per second. It follows from Fick's law that at any given point in the medium, the concentration of the diffusing entity A will change with time at a rate governed by the variation of the flux with distance [$\partial c/\partial t = \partial/\partial x(D \partial c/\partial x)$]; for the particularly simple case where D is independent of

distance, as in self-diffusion, then $\partial c/\partial t \approx D \partial^2 c/\partial x^2$]. Also, from the theory of random flights, it can be shown that the root-mean-square displacement of atoms resulting from diffusion for a time t increases as the square root of the product Dt : $R_{rms} = (6Dt)^{1/2}$.

It is observed that for any given system, D increases rapidly with increasing temperature, almost invariably following the Arrhenius relation $D = D_0 \exp(-H/RT)$. Here, D_0 and H are positive constants for a given system and R is the universal gas constant. The parameter H is called the activation energy and generally increases as the melting point of the host crystal increases. Typically, in crystals which melt at 400 to 500°C, H is about 20,000 to 25,000 cal/mole, or 1 eV/atom, for self-diffusion or diffusion of substitutionally dissolved impurities. In crystals which melt near 1000°C, such as the noble metals, the activation energy is approximately 2 eV/atom. The value of the parameter D_0 is usually in the range 0.01 to 100 cm²/sec. It is interesting that for a large number of metals and simple ionic crystals, the diffusion coefficients for self-diffusion and for most impurities lie near to 10^{-8} cm²/sec at temperatures approaching the melting point. Thus, after diffusing for one day at such a temperature, the value of R_{rms} is about 1 mm, rather a large distance when compared to the spacing between atoms in a crystal.

Because of the three-dimensional regularity of atomic positions in a crystalline solid, the unit step in diffusion must be the jump of an atom from one site to a neighboring, crystallographically equivalent site. Large-scale diffusion is the result of random superposition of many such jumps, all of the same length λ but distributed among the various jump directions allowed by the crystal. It is readily shown that the relation between the macroscopic diffusion coefficient D and the microscopic atomic jump frequency Γ is $D = 1/6 \lambda^2 \Gamma$. This equation may be compared with that given above for R_{rms} by noting that for random jumps $R_{rms} = \lambda(\Gamma t)^{1/2}$. Now λ will depend on the details of the mechanism of diffusion but it must be of the order of the interatomic spacing, about 3×10^{-8} cm. Then the typical high-temperature diffusion coefficient of 10^{-8} cm²/sec requires each atom to make 10^7 to 10^8 jumps each second.

In most crystals the atoms are rather densely packed; thus the means whereby such a high frequency of jumps can be accomplished is not obvious. Conceptually, the simplest possibility is the simultaneous exchange of sites between two atoms, but this is ruled out because of the excessive activation energy that would be required to push aside the mutual neighbors of the pair. A dramatic demonstration that diffusion must proceed by a mechanism which allows independent motion of individual atoms is the Kirkendall effect. Two mutually soluble specimens of differing composition, say A and B, are welded together with inert markers imbedded at the interface. Subsequent interdiffusion of A and B results in a drift of the markers relative to the ends of the specimen,

indicating that more atoms have left one side of the couple than have entered it from the other. Clearly a pair exchange mechanism cannot be operative here.

Extensive evidence is now available that in most cases of self-diffusion or of substitutionally dissolved impurities, migration proceeds as a result of the presence and mobility of vacant lattice sites. These vacancies exist in the crystal in thermodynamic equilibrium, at concentrations which increase with temperature as $\exp(-H_f/RT)$, where H_f is the energy required to form a vacancy (about 1 eV in the noble metals). At temperatures near the melting point, the fraction of sites vacant is typically 0.01 to 0.1 per cent. Vacancies move by the jumping of adjacent atoms, at a rate which varies as $\exp(-H_m/RT)$. H_m is the activation energy for the migration process. The average jump frequency of an atom must then be the product of the jump frequency of a vacancy and the fraction of atomic sites that are vacant. Comparing the temperature dependence of the diffusion coefficient with that of these two factors, it follows that H must equal the sum of H_m and H_f . Quantitative experimental verification of this equality in a number of substances has firmly established the vacancy mechanism for diffusion in such crystals.

There are cases, however, where other mechanisms are known to operate. First, diffusing atoms migrate from one interstitial position (i.e., squeezed in between proper atom sites) to another when the migrating atom is very small (carbon in iron), when the host atoms and diffusing atoms are easily deformed (diffusion of silver ion in silver bromide), and occasionally in crystals which are not densely packed (copper in silicon). Second, when the temperature is so low that diffusion through the volume of the crystal is very slow, all substances show "short-circuiting" effects due to migration along external surfaces, grain boundaries, and line defects called dislocations. The details of these processes are incompletely understood at present.

DIODE (SEMICONDUCTOR)

There exists a class of two terminal devices which have the property of permitting current to flow with practically no resistance in one direction and offer nearly infinite resistance to current flowing in the opposite direction. These devices are called *diodes*. The applications of diodes to electronic circuits are numerous. To mention a few, they include rectification of alternating current to a unidirectional current, detection of radio waves, and gating circuits used in digital computers.

The basic materials utilized for making semiconductor diodes are germanium (Ge) and silicon (Si). These elements are included in column IV of the periodic table (see PERIODIC LAW AND PERIODIC TABLE). Both Ge and Si are *tetravalent* elements, i.e., they have 4 valence electrons. Elements in their pure state are said to be *intrinsic*.

Each element under column III of the periodic table has 3 valence electrons and is referred to as *trivalent*. Examples of trivalent elements include indium (In) and gallium (Ga). Elements in column V of the table have 5 valence electrons and are called *pentavalent*. Arsenic (As) and antimony (Sb) are examples of pentavalent elements.

The process of introducing one of the elements from column III or V into intrinsic Ge or Si is called *doping*. The doped material becomes impure or *extrinsic*. If a trivalent impurity is introduced in Ge or Si (trivalent elements have one *less* valence electron than Ge or Si) holes are created and the material is said to be *p*-type. Introduction of a pentavalent impurity (pentavalent elements have one *more* valence electron than Ge or Si) creates free electrons and the material is *n*-type.

Because of thermal effects, free electrons and holes are always being produced in Ge and Si (intrinsic generation of electron-hole pairs). Consequently, there will be some electrons in the *p*-type material and some holes in the *n*-type material. These carriers are referred to as *minority* carriers. Electrons in *n*-type material and holes in *p*-type material are termed *majority* carriers.

There are two important kinds of semiconductor diodes: point-contact and *p-n* junction types. The operation of the point-contact diode is imperfectly understood whereas the operation of the junction diode is well known. The junction diode is most widely used; the point-contact type finds greatest use in high-frequency applications.

A typical point-contact structure is illustrated in Fig. 1. An S-shaped wire a few mils in diameter, called a cat's whisker, is pressed against a small wafer of doped semiconductor material. A point contact is formed. Assuming the semiconductor material is *n*-type Ge (or Si), a current of 100 to 200 mA is passed through the cat's whisker, point contact, and wafer for a length of time up to 100 msec. A *p-n* junction is formed and the point-contact diode obtained.

Considering the junction diode, imagine a

FIG. 1.

single crystal of Ge (or Si) doped so half the material is *p*-type and the other half, *n*-type. The internal boundary between the two extrinsic regions is a *p-n* junction, and the resulting device is a junction diode (Fig. 2). The electrical symbol for the point-contact and junction diodes is illustrated in Fig. 3.

FIG. 3.

What are the characteristics of the *p-n* junction? To answer this question, three possible conditions are considered. Referring to Fig. 4(a), these are:

(1) *Unbiased*: *p*- and *n*-sides are connected by a wire.

(2) *Reverse biased*: the *p*-side is connected to the negative terminal of battery *E*, and the *n*-side connected to the positive terminal.

(3) *Forward biased*: the *p*-side goes to the positive terminal of *E*, and the *n*-side to the negative terminal.

Simple energy diagrams for the three conditions are shown in Fig. 4(b) for the electron. Similar diagrams can be generated for holes. When the diode is unbiased, no net flow of electrons takes place across the junction. Assuming that some electrons on the *n*-side have sufficient energy to overcome the potential hill, electrons on the

FIG. 4.

p-side (minority carriers) "slide down" the hill making the net current flow zero. For the reverse biased case, the potential hill is raised and only the few minority carriers from the *p*-side "slide down". This results in a minute reverse saturation current. When the diode is forward biased, the potential hill is lowered. This enables electrons to climb over the hill and current flow occurs. The same considerations apply to holes. In fact, the total diode current is equal to the sum of the electrons and holes flowing across the junction.

The characteristic curve of a semiconductor diode is shown in Fig. 5. An equation for this

FIG. 5.

curve, called the *rectifier equation*, is expressed as:

$$I = I_s(e^{-11600 E / T} - 1)$$

where

I = diode current, amperes

I_s = reverse saturated current (which is temperature dependent), amperes

E = diode biasing voltage (+ E for forward bias; - E for reverse bias), volts

T = absolute temperature ($^{\circ}\text{C} + 273^{\circ}$), degrees Kelvin.

At room temperature (300°K) and $E > 0.1$ volt:

$$I \approx I_s e^{39 E}$$

When E is more negative than 0.1 volt:

$$I \approx -I_s$$

DIPOLE MOMENTS (ELECTRICAL AND MAGNETIC)

Uncharged molecules can be classified as non-polar or polar depending on whether, in the absence of an electric field, the centers of gravity of their constituent positive and negative charges are coincident or not. A body containing two opposite charges, $\pm Q$, separated by a distance d , is characterized by an electric dipole moment, $Qd = \mu$; μ is a vector quantity, expressed conveniently in debye (D) units: 1 debye = 10^{-18} esu = 3.33×10^{-30} [coul m].

In the presence of an applied field a normally nonpolar molecule becomes dipolar by induction, i.e., by deformation of its electronic and atomic arrangements: $\mathbf{m} = (\alpha_e + \alpha_a)\mathbf{E}$, where the coefficients of proportionality α_e and α_a are

the electronic and atomic polarizabilities, respectively. In the general case of an anisotropically polarizable molecule, α_e and α_a are tensors, the components of which may be evaluated from observations of electric birefringence (Kerr effect), the depolarization of (Rayleigh) scattered light, refractive index dispersion, etc. An estimate of the mean of the three principal polarizabilities is given by $3R/4\pi N$, where R is a molecular refraction by the Lorenz-Lorentz formula; when R is extrapolated to infinite wavelength the mean polarizability obtained refers to the electronic deformations alone. Polarizabilities are expressed in volume units (cubic centimeters) (N = the avogadro number).

A field E exercises a torque on an electric dipole μ , tending to align it in the field direction in opposition to the randomness caused by thermal agitation. In a large assembly of molecules, therefore, a statistical and temperature-dependent equilibrium is achieved which corresponds to a slight excess of molecules having their permanent dipoles oriented antiparallel to the field so that the average moment \bar{m} of one molecule is apparently proportional to the field intensity, i.e., an orientation polarizability α_o is exhibited.

The electric dipole moment per unit volume of a dielectric material is the polarization vector P , understandable in magnitude as the charge density bound at the electrodes by a polarized dielectric. Based on the arguments of Mossotti (1850) and Clausius (1879), the polarization per mole is related to the dielectric constant ϵ by $M(\epsilon - 1)/d(\epsilon + 2) = 4\pi N\alpha/3$, where M/d is the molecular volume, N is the avogadro number, and α is the over-all polarizability. Debye (1912) showed α_o to be $\mu^2/3kT$ (k = Boltzmann's constant, T = absolute temperature) so that $\alpha = \alpha_e + \alpha_a + \alpha_o$, and the total polarization per mole τP is the sum of the electronic, atomic, and orientation polarizations: $\tau P = \epsilon P + \alpha P + \alpha_o P$. A possible fourth polarization mechanism, the blocking or trapping of migrating charge carriers in a dielectric, although ignored in the classical molecular theory, may also contribute to the apparent ϵ of solid or macromolecule-containing systems.

The commonest method for the determination of dipole moments involves the dispersion of ϵ : τP is measured at radio and optical wavelengths (the second of these is a molecular refraction since the square of the index of refraction of a nonabsorbing, nonmagnetic material equals the dielectric constant at the same frequency), then approximately $R = \epsilon P + \alpha P$, and $\mu^2 = 9kT(\tau P - R)/4\pi N$. Although strictly valid only for gaseous dielectrics the Mossotti-Clausius-Debye equations have proved applicable also to solutes in nonpolar solvents, and by using alligation formulas, values of τP for a dissolved species can be obtained at infinite dilution; such estimates are usually close to, but not identical with, the true τP 's directly observed on the vaporized solutes. Over the past thirty years, much effort has been devoted to theoretical or empirical

treatments of "solvent effects." Since distortion polarizations are almost invariant with temperature, the temperature dependence of τP follows as $(\tau P)_T = A + B/T$; the constants A and B , when fitted to experimental data by least squares, give $A = \epsilon P + \alpha P$ and $B = 4\pi N\mu^2/9k$, whence $\mu = 0.012812B^{0.5}$ esu; results for about 350 gases are listed by Marryott and Buckley.

Practical details concerned with the measurement of dielectric constants, and other properties, necessary for the deduction of μ 's of solutes or vapors, are described fully in the books (cited below) by Le Fèvre, Smith, and Smyth, wherein also references are made to other, but less simple, techniques by which dipole moments can be determined (e.g., Stark splitting in microwave spectra of gases at low pressures, the dielectric losses or power factors of dilute solutions, molecular beam studies, etc.); the first two of these are useful since they can detect very small moments which the ordinary dielectric constant methods cannot reveal accurately; the third technique—involving the deviation undergone by a thin ribbon of gaseous molecules in passing through an intense nonhomogeneous electric field—is applicable to substances, such as metal salts, which through insolubility or low volatility would be otherwise unexaminable.

By the end of 1961, some 7000 dipole moment values for more than 6000 substances had been recorded (see McClellan's Tables); they fall mostly in the range 0 to 5 debyes.

Chemical interest is largely due to the relationships between polarity and molecular structure. Monatomic molecules, diatomic molecules of the type AA , and centrosymmetric polyatomic molecules, are nonpolar; a linear triatomic molecule ABA is nonpolar, but if bent or constructed as AAB it is polar; pyramidal tetraatomic molecules AB_3 are polar, etc. A more quantitative approach supposes that characteristic polarities are associated with covalent chemical bonds, e.g., that two bonds, having "bond moments" μ_1 and μ_2 , mutually inclined at θ° , produce a resultant of $(\mu_1^2 + \mu_2^2 + 2\mu_1\mu_2 \cos \theta)^{0.5}$. On this basis, bond moments deduced from the resultant moments of molecules with known structures, often permit the discovery or testing of stereo specifications of further molecules. However, caution is necessary since bond moments are not independent of bond environments, but may be modified by induced moments—determined by the fields of neighboring polar bonds or centers and the (anisotropic) polarizabilities of the bonds under consideration—or by other internal electronic effects (c.f. resonance, mesomerism, hybridization, etc.). Completely successful calculations of dipole moments from *a priori* theory have yet to be made.

Some concepts developed for electrostatic fields have magnetic counterparts; thus in place of polarization P there is magnetization I , the magnetic dipole moment per unit volume caused in a material by an externally applied field H ; internally the magnetic flux density (the magnetic induction) is $B = H + 4\pi I$; the ratio I/H is the

volume susceptibility κ ordinarily measured. Individual magnetic monopoles are not known to exist in nature, but movements and spins of electrons in atoms and molecules—if viewed classically as direct currents flowing in closed circuits—can create fields identical with those expected from magnetic dipoles having moments dimensionally equivalent to products of pole strengths and distances. The elementary magnetic moment is the "Bohr magneton," 9.273×10^{-21} [erg gauss⁻¹], assumed to be the magnetic moment of an electron "spinning" on its own axis. Atoms may possess orbital moments (due to mechanical angular movements of electrons) and spin moments (one for each electron). Magnetic moments can be induced or permanent. A unit volume containing ν particles each of magnetizability α_m , subjected to a field H , displays a magnetization $I = \nu\alpha_m H = \nu\bar{m}$, where \bar{m} is the average magnetic dipole moment per particle; thus $\kappa = \nu\alpha_m$, and the molar susceptibility $\chi = \kappa V = N\alpha_m$ (where V is the molar volume and N the avogadro number); α_m can be split into $\alpha_i + \alpha_p$, to correspond with the contributions to I made by the induced and permanent moments respectively.

An electron, in an orbit of radius r represents a current loop; application of a magnetic field H perpendicularly to the loop plane will induce a voltage tending to create a field opposing that applied; the effect will be manifest as an apparent induced moment antiparallel to H and—by classical calculations—of the value $-e^2 r^2 H / 6mc^2$ (here e is the electronic charge, m is the electronic mass, c is the velocity of light); hence $\alpha_i = -e^2 r^2 / 6mc^2$, and for a monatomic substance with spherical atoms the molar diamagnetic susceptibility $\chi = -(Ne^2 / 6mc^2) \sum_n r_i^2$, where r_i^2 is the mean value of r^2 for the i th electron and the sum is taken over n electrons. The χ 's observed for the inert gases, the C atoms in diamond, the Cl atoms in Cl_2 , etc. have agreed with reasonable magnitudes of $\sum r^2$. Pascal (1910) showed diamagnetic susceptibility to be an "additive-constitutive" property, so that the χ 's of polyatomic molecules can be approximately predicted by summing "atom" and "bond" susceptibilities in numbers and kinds appropriate to the molecular structure under consideration. The diamagnetic susceptibility of an individual molecule is a tensor quantity; χ/N by experiment is an average of three principal magnetic susceptibilities directed along three mutually perpendicular principal axes of magnetic susceptibility; these can be investigated through torsional movements of crystals in magnetic fields (Krishnan's method) or from magnetic birefringence measurements (Cotton-Mouton effects) in conjunction with data for χ_{mean} secured with a Gouy balance.

A permanent magnetic dipole will experience a torque in a magnetic field. Langevin (1905) showed that the mean moment \bar{m} of a gaseous molecule in the field direction (provided that H is not too large) is $\bar{m} = (m_p^2 / 3kT)H$, where m_p is the actual moment of each molecule; therefore the molar paramagnetic susceptibility χ_p is

$N\bar{m}/H = N\alpha_p = Nm_p^2 / 3kT$. In practice χ_p is extracted from the observed χ by treating this as the algebraic sum of a negative diamagnetic susceptibility (estimated from Pascal's constants) and a positive paramagnetic susceptibility; thus m_p follows as $(3kT\chi_p/N)^{0.5}$ [erg gauss⁻¹] or as $2.84(T\chi_p)^{0.5}$ [Bohr magnetons]. Molar diamagnetic susceptibilities are independent of temperature, while molar paramagnetic susceptibilities in general vary as $1/T$ or $1/(T - T_c)$. The small paramagnetisms of alkali metals, Cu, Ag, etc., or of certain salts (e.g., KMnO_4 or $\text{K}_2\text{Cr}_2\text{O}_7$), attributable respectively to uncompensated spins of conduction electrons, or to uncompensated paramagnetisms of complex ions, are temperature invariant.

Normally any atom or molecule with unpaired electrons shows paramagnetism and possesses a magnetic moment. Magnetic properties can therefore provide important information on valency states in free radicals, molecules containing first period elements with unpaired p electrons, transition elements having unpaired d electrons, lanthanides with unpaired $4f$ and actinides with unpaired $5f$ electrons. Theoretical expressions exist to calculate paramagnetic moments in terms of atomic structures and spin and orbital angular momenta of unpaired electrons. Simple examples are the ions of transition metals where, if n is the number of unpaired electrons, m_p is approximately predicted as $[n(n + 2)]^{0.5}$ Bohr magnetons (for a full discussion of such relations see Nyholm's review). Determination of m_p thus gives n , which is often of value in deciding the three-dimensional arrangements and bond types involved in molecules, especially those built around a central metal atom.

For most substances χ is independent of field strength, but a few paramagnetic compounds can, below the characteristic temperature T_c (see above), show "ferromagnetism" due to spontaneous parallel alignments of spins of atomic magnets. Materials which are ferromagnetic at ordinary temperatures (e.g., soft iron) have nonlinear magnetization-field characteristics, develop large magnetizations in weak fields, rapidly approach saturation conditions, exhibit hysteresis, etc.; whole domains about 0.01 mm in diameter and magnetically saturated are thought to be undergoing orientation during such processes. Ferromagnetism—and related phenomena such as "antiferromagnetism" and "ferrimagnetism"—have at present few applications in chemistry; in electronics (e.g., ferrites in antennas and in magnetic tape), they are frequently important.

DOPPLER EFFECT

The wave effect by which astronomers measure the radial velocities of galaxies, and policemen determine the speeds of approaching automobiles, was in spite of its simplicity not discovered until the nineteenth century. In 1842, Christian Doppler predicted that the frequencies of received waves were dependent on the motion of the source or observer *relative to the propagating medium*. His predictions were promptly checked for sound waves by placing the source or observer on one of the newly developed railroad trains.

In his original article on the special theory of relativity (see RELATIVITY), Einstein¹ developed the expression for the Doppler shift of light waves which was dependent upon the velocity of the source *relative to the observer*. From the photon hypothesis for light, Schrödinger^{2,3} obtained the same results. Thus, the Doppler effect provides one of the illustrations of the equivalence of the wave and particle descriptions of light.

Classroom demonstrations of the Doppler effect for water waves are made in shallow glass-bottom ripple tanks. Instead of giving the vibrating source a constant velocity, one lets the sheet of water as medium flow continuously by the source.

The circles of Fig. 1 are snapshots of the crests of a water wave or compressions in a sound wave observed when the source is moving at constant velocity v to the right relative to the medium. Points 1 and 2 are positions of the source one and two periods after passing O. The largest circular crest originated at O, the next at 1 and the smallest at 2. A crest is about to leave point 3 at the time the snapshot is taken. If the position P of the observer is a large distance from the source compared to the distance the source moves in one period, then with good approximation we may assume that two successive crests are moving in the same direction as they pass P. If v is the velocity of the source in the direction OA, the source moves a distance vT in one period T . In

FIG. 1. The source is moving relative to the medium along the line BA. The circles represent crest of the wave at an instant. (Andrews, C. L., "Optics of the Electro-Magnetic Spectrum", Englewood Cliffs, N.J., Prentice-Hall, Inc., 1960).

one period, the source comes closer to P by the amount $vT \cos \theta$, where θ is the angle between the direction of the velocity of the source and the line from the source to the observer at P. Now λ_0 is the wavelength and ν_0 the frequency when the source is at rest; λ is the observed wavelength and ν the observed frequency when the source is in motion. Because of the motion of the source, the wavelength received at P is reduced by $vT \cos \theta$.

$$\lambda - \lambda_0 = vT \cos \theta$$

If c is the velocity of the wave, $T = \lambda_0/c$ and $\lambda = \lambda_0 \left(1 - \frac{v}{c} \cos \theta \right)$, but $\lambda = c/\nu$ and $\lambda_0 = c/\nu_0$. Therefore,

$$\frac{\nu}{\nu_0} = \frac{1}{1 - \frac{v}{c} \cos \theta} \quad (1)$$

when the source is in motion relative to the medium.

In Fig. 2 the source is at rest, but the observer at P has a velocity v with respect to the medium. The velocity of the wave relative to the observer is equal to the vector sum of the velocity of the wave relative to the medium and the velocity of the medium relative to the observer. In Fig. 2, c is the velocity of the wave and v the velocity of the observer relative to the medium. Let λ_0 be the wavelength, ν_0 the frequency of the source, and ν the frequency received by the moving observer. The radial velocity of the wave relative to the observer is $c + v \cos \theta$ so that

$$\nu \lambda_0 = c + v \cos \theta$$

For an observer at rest $\nu_0 = c/\lambda_0$. Substituting for λ_0 , we obtain

$$\frac{\nu}{\nu_0} = 1 + \frac{v}{c} \cos \theta \quad (2)$$

FIG. 2. The source is at rest at point O and the observer at point P is moving with velocity v relative to the medium. (Andrews, C. L., "Optics of the Electro-Magnetic Spectrum," Englewood Cliffs, N.J., Prentice-Hall, Inc., 1960).

when the *observer* is in motion relative to the medium.

By a postulate of relativity, the velocity of light is the same relative to all observers. The theory of relativity yields the frequency

$$\frac{\nu}{\nu_0} = \frac{1 + \frac{v}{c} \cos \theta_0}{\sqrt{1 - \frac{v^2}{c^2}}} \quad (3)$$

in which $v \cos \theta_0$ is the component of the velocity of the source toward the observer. The angle θ_0 is measured in the source system. If θ is the angle measured in the observers system, then

$$\cos \theta_0 = \frac{\frac{v}{c} \cos \theta}{\frac{v}{c} \cos \theta - 1} \quad (4)$$

Figure 3 is a graphical plot of ν/ν_0 against v/c for the radial motion in the three cases we have treated. (1) The linear relation is that for the observer in motion relative to the medium that propagates sound or other mechanical waves. (2) The other solid curve is for the source of sound in motion. (3) The broken curve represents the Doppler effect for electromagnetic waves such as x-rays, light, and radio waves.

By comparing several spectral lines of elements observed in a star with a laboratory spectrum of the same elements, astronomers use the Doppler effect to measure the radial components of velocity of astronomical bodies toward or away from the earth. Spectra of the edges of the sun's disk are measured to determine the velocities toward and away from the earth. The radial velocities of the principal stars of our galaxy have

FIG. 3. Graphical plots of the ratio of the observed frequency to the frequency at the source against the ratio of radial velocity to the velocity of the wave for three cases: (1) sound waves from a moving source, (2) sound waves to a moving receiver, (3) electromagnetic waves. The circle represents the red shift of light received from the most distant galaxies observed.

been recorded. The spectral lines of some of the stars are doublets which periodically come together and separate again indicating that the light comes from two stars revolving about a common center of gravity (see ASTROMETRY).

In the expanding universe, the radial velocities of other galaxies away from our galaxy are proportional to their distances from the observer. Thus, the Doppler red shift provides a means of determining the dimensions of the observed universe. In 1964, some of the most intense radio sources (see RADIO ASTRONOMY) were located with high precision by observing these sources when the moon passed in front of them. With this knowledge of position, the same sources were located with a light telescope.⁴ The measured red shift was surprisingly high. The sources were not stars as previously thought but the most distant galaxies known. One of them, 3C-9 in the catalogue of radio sources had a red shift $\Delta\lambda/\lambda_0$ equal to 2.0. If this shift were due solely to the Doppler effect, the astronomers had to conclude that the source was moving from us with 80 per cent of the velocity of light. The Doppler frequency and velocity of this source is indicated by a circle on the broken line of Fig. 3.

If a microwave beam is reflected from a moving microwave mirror, such as a person, an automobile or a man-made satellite, the image of the primary source may be considered as another source moving with twice the velocity of the mirror. Since the speed is small compared with the

speed of light, the squared terms of Eq. (3) may be neglected. Thus

$$\nu = \nu_0 \left(1 + \frac{2v}{c} \cos \theta \right)$$

Direct frequency measurements cannot be made to enough significant figures to distinguish ν from ν_0 . However, if the two frequencies are combined they give beats or the difference frequency

$$\Delta\nu = \nu_0 \frac{2v}{c} \cos \theta$$

Since the beat frequency is proportional to the radial velocity, a frequency meter may be calibrated in miles per hour. The precision of such a speed detector depends upon the frequency of the source being so stable that it varies less than the Doppler frequency shift during the time that the wave travels from the source to the mirror and back. The same phenomena of beats between the direct wave from the source and the wave reflected from a moving mirror may be observed with light. If one of the mirrors of Michelson's interferometer is moved at constant speed, the frequency with which dark bands pass the cross hair is the difference in frequency of the two waves.

The numerator of Eq. (3) contains a term for the radial component of velocity. However, the second-order term in the denominator is independent of direction. Thus, as v/c approaches unity, one may expect to detect a *tangential Doppler effect*. Ives and Stilwell⁵ have measured the predicted value for the Doppler shift in frequency due to a stream of radiating molecules for which v/c was 10^{-2} . This experiment was a direct proof of time dilatation (see RELATIVITY) for the transverse case. In order to separate the tangential from the radial effect, Ives and Stilwell produced a sharply collimated beam of molecules. In order that θ be precisely 90° , they set a mirror accurately normal to the line of observation and altered the line of observation until nearly the same wavelengths were given by direct and reflected light.

DYNAMICS

Introduction. A recent Webster's definition of the word *dynamics* is "That branch of MECHANICS treating of the motion of bodies (kinematics) and

the action of forces in producing or changing their motion (kinetics)."^{*}

This order of presentation is often utilized in textbooks and other treatises on the subject. With various interpretations of the word *bodies*, the subject has also been divided into the areas of particle dynamics, rigid body dynamics, and fluid dynamics. As needs have developed, various specializations have been created and new theories have been formulated. These special areas include mechanical vibrations, flight dynamics, space dynamics, gas dynamics, magnetohydrodynamics, and relativistic dynamics, to mention a few.

The present state of knowledge recognizes all motion as relative, since no fixed reference is known for finding the absolute motion of any body. The earth, which is frequently used as a frame of reference is rotating about its own axis and is also revolving about the sun. The solar system, which consists of the sun and its planets, is a minute part of the Milky Way galaxy that is known to be revolving in space.¹ Beyond this, there is limited knowledge of the nature of motion that exists.

In the field of astronomy, measurements are evaluated in a coordinate system that is located relative to the *fixed* stars. These stars are located at such a vast distance from the earth that they appear as points of light that are almost motionless in space. In this frame of reference, the motions of celestial bodies are described with extremely great precision, and the motions of bodies within the solar system can be predicted accurately over periods of hundreds of years.

Some applied areas of dynamics, exemplified by the space exploration program[†], also require the degree of extreme accuracy that is possible with a celestial frame of reference. In many other areas, this extreme accuracy is not essential and measurements based upon this frame of reference would be tedious and impractical. In such cases, motion may often be adequately described in a coordinate system located relative to the earth.

Kinematics. A particle is a body having dimensions that are small, relative to other dimensions of the system, so that its motion may be considered equivalent to the motion of a point at its mass center with rotational effects neglected. Thus, particles may be either small or large. In the solar system, it would be possible to assume the earth to be a particle but, in a terrestrial system, this assumption could be totally unjustifiable.

A rigid body is a group of particles having unvarying external and internal configuration. The size of the rigid body would be appreciable in comparison to the other dimensions of the system, so that the rotational effect would have to be considered.

A fluid body is a group of particles with varying external and or internal configuration.

^{*} By permission. From Webster's New Collegiate Dictionary, copyright 1956 by G. & C. Merriam Co., Publishers of the Merriam-Webster Dictionaries.

The analysis of this type of system will not be considered in this article. (See FLUID DYNAMICS.)

The kinematic analysis of the motion of a particle may be approached through the establishment of a position VECTOR \mathbf{r} , directed from the origin of a specified fixed coordinate system to the point representing the position of the particle, to give

$$\mathbf{r} = x\mathbf{i} + y\mathbf{j} + z\mathbf{k} \quad (1)$$

where \mathbf{i} , \mathbf{j} and \mathbf{k} are unit vectors along the x , y and z axes, respectively. Differentiating Eq. (1) with respect to time yields a velocity equation of the form

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \frac{dx}{dt}\mathbf{i} + \frac{dy}{dt}\mathbf{j} + \frac{dz}{dt}\mathbf{k} \quad (2)$$

A second differentiation with respect to time yields the acceleration of the particle in the form

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{d^2\mathbf{r}}{dt^2} = \frac{d^2x}{dt^2}\mathbf{i} + \frac{d^2y}{dt^2}\mathbf{j} + \frac{d^2z}{dt^2}\mathbf{k} \quad (3)$$

If x , y and z are scalar functions of time, then Eq. (1), (2) and (3) may be used to trace the path of the particle and determine the velocity and acceleration at any instant. These equations may be easily adapted to the cases of rectilinear translation and curvilinear translation of a particle in plane motion.

The kinematic analysis of a rigid body moving in a plane often involves the trace of two points, which may be called A and B, that are located on the body. These points move with the body and remain a fixed distance apart. Two coordinate systems may be used to define the position of the body in the plane. An X - Y coordinate system, with origin O , is a fixed reference, and an x - y coordinate system, with origin o located at A, is attached to the body so that it moves and rotates with the body. In the fixed reference system, a position vector \mathbf{R} is directed from O to point A on the body and a second position vector $\boldsymbol{\rho}$ is directed from O to point B. In the moving coordinate system, a vector \mathbf{r} is directed from A to B. An equation relating the position of the two points may be written as

$$\boldsymbol{\rho} = \mathbf{R} + \mathbf{r} \quad (4)$$

Using the \mathbf{I} , \mathbf{J} , \mathbf{K} unit vectors for the X - Y - Z coordinate system and the \mathbf{i} , \mathbf{j} , \mathbf{k} unit vectors for the x - y - z coordinate system, Eq. (4) may be rewritten as

$$\boldsymbol{\rho} = X\mathbf{I} + Y\mathbf{J} + x\mathbf{i} + y\mathbf{j} \quad (5)$$

Differentiating Eq. (5) with respect to time yields the velocity of B in the form

$$\mathbf{v}_B = \frac{d\boldsymbol{\rho}}{dt} = \frac{dX}{dt}\mathbf{I} + \frac{dY}{dt}\mathbf{J} + \frac{dx}{dt}\mathbf{i} + x\frac{d\mathbf{i}}{dt} + \frac{dy}{dt}\mathbf{j} + y\frac{d\mathbf{j}}{dt} \quad (6)$$

which simplifies to

$$\mathbf{v}_B = \mathbf{v}_A + \mathbf{v}_{B/A} \quad (7)$$

where \mathbf{v}_B and \mathbf{v}_A are the velocities of points B and A, respectively, and $\mathbf{v}_{B/A}$ is the velocity of point B relative to point A.

A second differentiation of Eq. (5) with respect to time yields the acceleration of B in the form

$$\mathbf{a}_B = \mathbf{a}_A + \mathbf{a}_{B/A} \quad (8)$$

where \mathbf{a}_B and \mathbf{a}_A are the accelerations of points B and A, respectively, and $\mathbf{a}_{B/A}$ is the acceleration of point B relative to point A.

A second important case of rigid body motion exists when point B is not attached to the same body as point A but is moving along a constrained path on this body. For the analysis of this motion, it is convenient to designate the fixed reference as body 1, the body to which point A is attached as body 2, and the body to which point B is attached as body 3. The same general arrangements of coordinate systems are used but in this case, the fixed X - Y coordinate system may be considered as attached to body 1 while the moving x - y coordinate system is attached to body 2. In the general case, vector \mathbf{r} within the x - y coordinate system is varying in both magnitude and direction. Differentiating the position expression

$$\boldsymbol{\rho} = \mathbf{R} + \mathbf{r} \quad (9)$$

once with respect to time and simplifying yields

$$\mathbf{v}_{B3} = \mathbf{v}_{A2} + \mathbf{v}_{B2/A2} + \mathbf{v}_{B3/2} \quad (10)$$

where \mathbf{v}_{B3} is the velocity of point B on body 3, \mathbf{v}_{A2} is the velocity of point A on body 2, $\mathbf{v}_{B2/A2}$ is the velocity of point B on body 2 relative to point A on body 2, and $\mathbf{v}_{B3/2}$ is the velocity of point B on body 3 relative to body 2.

A second differentiation with respect to time gives

$$\mathbf{a}_{B3} = \mathbf{a}_{A2} + \mathbf{a}_{B2/A2} + \mathbf{a}_{B3/2} + 2\boldsymbol{\omega}_2 \times \mathbf{v}_{B3/2} \quad (11)$$

where \mathbf{a}_{B3} is the acceleration of point B on body 3, \mathbf{a}_{A2} is the acceleration of point A on body 2, $\mathbf{a}_{B2/A2}$ is the acceleration of point B on body 2 relative to point A on body 2, $\mathbf{a}_{B3/2}$ is the acceleration of point B on body 3 relative to body 2, $\boldsymbol{\omega}_2$ is the angular velocity of body 2, and $\mathbf{v}_{B3/2}$ is the velocity of point B on body 3 relative to body 2. The term $2\boldsymbol{\omega}_2 \times \mathbf{v}_{B3/2}$ is often referred to as the CORIOLIS component of acceleration.

Equations 7 and 8 may be adapted to the case of rotation of a rigid body about a fixed axis at point A by considering point A to be fixed. Thus, \mathbf{v}_A and \mathbf{a}_A are both zero and

$$\mathbf{v}_B = \mathbf{v}_{B/A} \quad (12)$$

$$\mathbf{a}_B = \mathbf{a}_{B/A} \quad (13)$$

For a body rotating about a fixed axis, analysis of the rotational motion yields

$$\frac{d\theta}{dt} = \omega \quad (14)$$

$$\frac{d\omega}{dt} = \alpha \quad (15)$$

where θ is the angular displacement in radians, ω is the angular velocity in radians per second, and α is the angular acceleration in radians per second per second. It should be noted that time may be expressed in other units.

Kinetics—Newton's Laws of Motion. The laws of Newton are based upon the motion of a particle relative to a fixed frame of reference in which the particle can be made completely free of all outside influences. Under such a condition, the particle at rest will remain at rest and a particle in motion will continue to move at a constant velocity. This ideal frame of reference is often referred to as a Newtonian or as an inertial frame of reference.²

Since it is not possible to actually establish the Newtonian frame of reference, Newton's laws of motion are used in a celestial or a terrestrial frame of reference. The gyroscopic instruments and the stabilized platforms represent attempts to achieve a fixed or stabilized frame of reference for aircraft or space vehicles.

In modern terminology, Newton's laws of motion for a particle may be interpreted as

(1) A particle tends to remain at rest or continues to move at a constant velocity if there is no unbalanced force acting upon it.

(2) An unbalanced force acting on a particle will produce a time rate of change of momentum which, at any instant, will be proportional to the force and will be in the same direction as the force.

(3) The forces that exist between two contacting particles are equal in magnitude, are opposite in direction, and are collinear.³

The concept of the first law is the fundamental principle used for the analysis of forces acting on stationary particles and also for the analysis of forces acting on particles moving with a constant velocity. The concept has been expanded to include rigid bodies and fluid bodies.

The second law is the foundation of the analysis of forces acting on particles moving with accelerations and, again, it has been extended to include rigid bodies which involve rotary motion and to include fluid bodies.

The third law is fundamental to the force analysis of interconnecting systems of particles under both static and dynamic conditions. It has also been extended to include simple contact between any pair of bodies and, with some modification, to include any type of interaction between bodies.

Force and Acceleration. In general, Newton's second law is stated as

$$\Sigma \mathbf{F} = k \frac{d(m\mathbf{v})}{dt} \quad (16)$$

where $\Sigma \mathbf{F}$ is the net unbalanced force on the particle; k is a constant of proportionality, consistent with the units used, that is determined

experimentally; m is the mass of the particle; and \mathbf{v} is the instantaneous velocity of the particle.

For a particle that is not shedding or accumulating mass, Newton's second law reduces to

$$\Sigma \mathbf{F} = k m \mathbf{a} \quad (17)$$

where $\Sigma \mathbf{F}$, k , and m are as previously defined and \mathbf{a} is the instantaneous acceleration of the particle. By the proper choice of units in Eq. (16) and (17), the constants of proportionality can be made equal to unity.

For a rigid body in plane motion, both translational and rotational acceleration must be considered. By extending the concept of Newton's second law, it may be stated that

$$\Sigma \mathbf{F} = k_1 m \mathbf{a} \quad (18)$$

$$\Sigma \mathbf{T} = k_2 I \alpha \quad (19)$$

where $\Sigma \mathbf{F}$ and $\Sigma \mathbf{T}$ are the unbalanced force and unbalanced torque, respectively, acting on the body; k_1 and k_2 are constants of proportionality, consistent with the units used, that are determined experimentally; m is the mass of the body; I is the mass moment of inertia of the body about a centroidal axis that is perpendicular to the plane of the motion; \mathbf{a} is the linear acceleration of the center of mass of the body; and α is the angular acceleration of the body. Again, with proper choice of units, k_1 and k_2 can be made equal to unity.

The concepts and equations presented herein can be applied for the solution of a wide variety of problems which involve systems of particles, systems of bodies, or combinations thereof. The usefulness of this approach may be further broadened by the introduction of the closely related concepts of energy and impulse—momentum.

It should be noted that, in Newtonian mechanics, the fundamental property of the particle is an unvarying mass and time is absolute. It should also be noted that when the speed of the particle approaches the speed of light, this theory becomes inaccurate in comparison to a theory based upon a more exact mathematical model attained through the application of the principles of RELATIVITY.⁴

E

ELASTICITY

Elasticity is the part of mechanics dealing with deformations that vanish entirely once the forces that have caused them are removed. Most solid bodies behave elastically for sufficiently small deformations, and we will be concerned here with the infinitesimal theory of elasticity. Also we will consider only isotropic bodies, that is, bodies whose elastic properties are the same in all directions.

The fundamental quantities in elasticity are second-order tensors, or dyadics: the deformation is represented by the *strain dyadic*, and the internal forces are represented by the *stress dyadic*. The physical constitution of the deformable body determines the relation between the strain dyadic and the stress dyadic, which relation is, in the infinitesimal theory, assumed to be linear and homogeneous. While for anisotropic bodies this relation may involve as much as 21 independent constants, in the case of isotropic bodies, the number of elastic constants is reduced to two.

Let $\mathbf{s}(\mathbf{r})$ be the displacement vector, due to the deformation, of a particle that before the deformation was situated at point P having \mathbf{r} as position vector with respect to some arbitrary origin. A neighboring point Q, whose position vector was $\mathbf{r} + d\mathbf{r}$ before the deformation, will suffer a displacement $\mathbf{s}(\mathbf{r} + d\mathbf{r})$ which will differ from $\mathbf{s}(\mathbf{r})$ by the quantity

$$d\mathbf{s} = d\mathbf{r} \cdot \nabla \mathbf{s}$$

The hypothesis of small deformations means that $d\mathbf{s}$, the change in the displacement vector when we go from P to the neighboring point Q, is very small compared to $d\mathbf{r}$, the position vector of Q relative to P. Consequently, the scalar components of the dyadic $\nabla \mathbf{s}$ are all very small compared to unity. The geometrical meaning of the dyadic $\nabla \mathbf{s}$ is obtained by separating it into its symmetric part $\mathbf{S} = \frac{1}{2}(\nabla \mathbf{s} + \mathbf{s} \nabla)$ and its antisymmetric part $\mathbf{R} = -\frac{1}{2}\mathbf{1} \times (\nabla \times \mathbf{s})$, where $\mathbf{1}$ is the unity dyadic. The antisymmetric part is interpreted as follows: if at some point M the symmetric part vanishes, then we have for the neighborhood of M the relation

$$d\mathbf{s} = d\mathbf{r} \cdot \mathbf{R}_M = \boldsymbol{\omega}_M \times d\mathbf{r}$$

where $\boldsymbol{\omega}_M = \frac{1}{2}(\nabla \times \mathbf{s})_M$ is an infinitesimal vector. This means that the neighborhood of point M undergoes an infinitesimal rigid rotation, without

any change in shape or size. Consequently, the deformation is represented by the symmetric part \mathbf{S} , which is called the *strain dyadic*.

In a Cartesian orthonormal basis, in which we have $\mathbf{r} = \sum_{i=1}^3 x_i \mathbf{a}_i$, we write $\mathbf{s} = \sum_{j=1}^3 s_j \mathbf{a}_j$, and obtain

$$\mathbf{S} = \sum_{i,j=1}^3 \mathbf{a}_i \mathbf{a}_j S_{ij}$$

where $S_{ij} = \frac{1}{2} \left[\frac{\partial}{\partial x_i} s_j + \frac{\partial}{\partial x_j} s_i \right]$. The diagonal components S_{11} , S_{22} , and S_{33} are the coefficients of linear extension in the directions \mathbf{a}_1 , \mathbf{a}_2 , and \mathbf{a}_3 , respectively, while the non diagonal components $S_{12} = S_{21}$, $S_{13} = S_{31}$, and $S_{23} = S_{32}$ are called shear strains. For instance, $2S_{12}$ is the change in the angle of the dihedron formed by the planes that before the deformation were respectively normal to the directions \mathbf{a}_1 and \mathbf{a}_2 . The shear strains are not essential for the complete representation of a deformation since they can be made to vanish by expressing \mathbf{S} in the basis of its principal axes.

If an infinitesimal element of the body occupies the volume dV before the deformation and the volume dV' after, the relative increase of volume, or volumetric dilatation, is given by

$$\frac{dV' - dV}{dV} = S_{11} + S_{22} + S_{33} = |\mathbf{S}| = \nabla \cdot \mathbf{s}$$

The forces applied to a finite deformable body are either body forces acting on every volume element dV and represented by the notation $dV \mathbf{F}$ or $dV \rho \mathbf{K}$, where \mathbf{F} is the force per unit volume, \mathbf{K} is the force per unit mass, and ρ is the density, or surface forces acting on every element dS of the bounding surface and represented by $dS \mathbf{T}$, where \mathbf{T} is the surface stress, or surface force per unit area. The effect of these applied forces is transmitted throughout the body, so that through any surface element inside the body, there is a force exerted by the matter on one side of the element upon the matter on the other side. Such forces are called internal stresses and are defined as follows: let dS be a surface element completely inside the body, and let us choose arbitrarily the positive sense of the normal \mathbf{n} to this surface element; this defines for dS a positive side, the one containing \mathbf{n} , and a negative side. Then \mathbf{T}_n ,

the stress vector on the positive side of dS is defined as a vector such that $dS \mathbf{T}_n$ is the surface force on the positive side of dS —i.e., the resultant of all the forces exerted through dS by the matter on the positive side of dS upon the matter on the negative side. In general there is a normal component $\mathbf{T}_n \cdot \mathbf{n}$, which is a pressure or a traction depending upon whether the sign of $\mathbf{T}_n \cdot \mathbf{n}$ is negative or positive, and a tangent component $\mathbf{n} \times \mathbf{T}_n \times \mathbf{n}$ called the shear stress. The value of the stress vector \mathbf{T}_n depends upon the orientation of the normal \mathbf{n} , so that we can characterize the state of stress at a point by defining the *stress dyadic* \mathbf{T} through the relation

$$\mathbf{T}_n = \mathbf{n} \cdot \mathbf{T}$$

The mechanical equilibrium conditions applied to an arbitrary volume V , bounded by the closed surface S , and completely inside the deformable body give

$$\int_V dV \mathbf{F} + \int_S dS \mathbf{n} \cdot \mathbf{T} = 0$$

and

$$\int_V dV \mathbf{r} \times \mathbf{F} + \int_S dS \mathbf{r} \times (\mathbf{n} \cdot \mathbf{T}) = 0$$

By the use of the divergence theorem, the first condition gives the equation

$$\nabla \cdot \mathbf{T} + \mathbf{F} = 0$$

at any point inside the body, and the second condition implies that \mathbf{T} is a symmetric dyadic. On the external surface of the body, we have usually to fulfill the boundary condition

$$\mathbf{n} \cdot \mathbf{T} = \mathbf{T}$$

where \mathbf{T} is the applied external force per unit area. Other boundary conditions can also be met, such that the value of the displacement be prescribed.

For infinitesimal deformations, we assume that the relation between strain and stress is expressed by Hooke's law: the deformation is proportional to the applied force. For isotropic bodies, this linear relation is

$$\mathbf{S} = \frac{1}{E} [(1 + \nu) \mathbf{T} - \nu |\mathbf{T}| \mathbf{1}]$$

where E is Young's modulus and ν is Poisson's ratio. These two elastic constants can be defined by considering the stretching of a cylindrical bar by normal traction forces uniformly distributed on the end sections; then we have

Young's modulus :

$$\frac{\text{Normal traction force per unit cross sectional area}}{\text{Relative longitudinal extension}}$$

and

$$\text{Poisson's ratio} = \frac{\text{Relative lateral contraction}}{\text{Relative longitudinal extension}}$$

We can also write

$$\mathbf{T} = 2\mu \mathbf{S} + \lambda |\mathbf{S}| \mathbf{1}$$

where $\mu = E/2(1 + \nu)$ and $\lambda = \nu E/[(1 + \nu)(1 - 2\nu)]$ are Lamé's constants. μ is the rigidity modulus, the only constant necessary when the volumetric dilatation vanishes everywhere.

Substituting the preceding relation into the equilibrium equations, we transform them into

$$2\mu \nabla \cdot \mathbf{S} + \lambda \nabla |\mathbf{S}| + \mathbf{F} = 0 \text{ inside the body}$$

and

$$2\mu \mathbf{n} \cdot \mathbf{S} + \lambda \mathbf{n} |\mathbf{S}| = \mathbf{T} \text{ on the bounding surface.}$$

These vector relations are not sufficient for the complete determination of the symmetric dyadic \mathbf{S} . To insure that a solution of the above equations correspond to a possible displacement vector \mathbf{s} , we must be able to integrate the relation

$$\mathbf{S} = \frac{1}{2} (\nabla \mathbf{s} + \mathbf{s} \nabla)$$

i.e., from a given expression for \mathbf{S} obtain the value of \mathbf{s} . From the vanishing of the curl of a gradient, it is easily seen that this integrability condition, also called the compatibility equation, is

$$\nabla \times \mathbf{S} \times \nabla = 0$$

By elimination of the vector products, we obtain the equivalent form

$$\nabla \nabla \cdot \mathbf{S} + \nabla \cdot \mathbf{S} \nabla - \nabla \nabla |\mathbf{S}| - \nabla \cdot \nabla \mathbf{S} = 0$$

Using the stress-strain relation and the equilibrium conditions, we obtain the Beltrami-Michell form of the compatibility equation:

$$\nabla \cdot \nabla \mathbf{T} + \frac{1}{1 + \nu} \nabla \nabla |\mathbf{T}| = - \frac{\nu}{1 - \nu} \nabla \cdot \mathbf{F} \mathbf{1} - (\nabla \mathbf{F} + \mathbf{F} \nabla)$$

Finally, by expressing the strain dyadic in terms of the displacement vector, we obtain Navier's form of the equilibrium equations:

$$\mu \nabla \cdot \nabla \mathbf{s} + (\lambda + \mu) \nabla \nabla \cdot \mathbf{s} + \mathbf{F} = 0 \text{ inside the body}$$

and

$$\lambda \mathbf{n} \nabla \cdot \mathbf{s} + 2\mu \mathbf{n} \cdot \nabla \mathbf{s} + \mu \mathbf{n} \times (\nabla \times \mathbf{s}) = \mathbf{T}$$

on the bounding surface.

Dealing here directly with the displacement vector, there is no need of considering the compatibility equation.

The propagation equation for elastic disturbances is obtained by adding the inertia force to the body force. We get then

$$\mu \nabla \cdot \nabla \mathbf{s} + (\lambda + \mu) \nabla \nabla \cdot \mathbf{s} + \rho \mathbf{K} = \rho \frac{\partial^2 \mathbf{s}}{\partial t^2}$$

inside the body.

The stress-strain relation and the boundary conditions are not affected, but we generally have to take into account initial conditions.

The energy density u , or energy per unit volume, is given by

$$u = \frac{1}{2} \mathbf{S} : \mathbf{T} + \frac{1}{2} \rho \frac{\partial \mathbf{s}}{\partial t} \cdot \frac{\partial \mathbf{s}}{\partial t}$$

where the first term is potential, or strain energy, and the second term is kinetic energy. The energy flux density vector

$$\mathbf{S} = \frac{\partial \mathbf{s}}{\partial t} \cdot \mathbf{T}$$

is a vector such that $d\mathbf{S} \cdot \mathbf{n}$ gives the quantity of energy that flows per unit time through the surface element $d\mathbf{S}$ in the positive direction of \mathbf{n} , the normal to $d\mathbf{S}$. At any point the energy continuity equation

$$\frac{\partial u}{\partial t} + \nabla \cdot \mathbf{S} - \rho \frac{\partial \mathbf{s}}{\partial t} \cdot \mathbf{K} = 0$$

expresses the conservation of mechanical energy.

ELECTRIC POWER GENERATION

About 95 per cent of the electric power produced in this country is by 3-phase generators. It is transmitted and distributed this way. Advantages of 3-phase generators lie in economy of apparatus, lower transmission losses, inherent starting torque for polyphase motors, and constant running torque for balanced loading. A generator is built with axial slots for armature coils in a stationary hollow cylindrical iron core called the stator. The windings are placed in the slots so that when carrying current they produce a chosen even number of alternate magnetic poles. The coils over each magnetic pole are grouped in 3 equal bands to give a 3-phase balanced system of terminal voltages.

An inner rotor has coils which carry direct current to give the same number of alternate magnetic poles as on the stator. Rotor current strength is controlled by a rheostat or voltage from a dc generator. Voltages are produced in the stator windings by flux cutting as the rotor magnetic flux sweeps by them, and currents flow when the

generator terminals are connected to a 3-phase load impedance. The 3-phase stator line voltages are equal in magnitude and 120 electrical degrees apart in time sequence. So also are the line currents for a balanced 3-phase load. Generator voltages are of the order of 12 000 to 30 000 volts for large machines.

Generator frequency is the product of the pairs of magnetic poles and the speed in revolutions per second. At 60 cycles, a 2-pole generator runs at 3600 rpm and a 6-pole generator at 1200 rpm. The maximum speed of 3600 rpm has been increasingly adopted even for very large machines because high speed means decreased size and weight for a given kilowatt rating and better steam-turbine performance. Waterwheels and water turbines show best characteristics at much lower speeds—roughly a range of 100 to 600 rpm. Sixty cycles is the prevailing frequency in this country for public utility power generation. Because of weight and space limitations, 400 cycles is found in the aircraft industry. Europe is basically on 50 cycles.

In the large central station steam power plants, single generators may reach, or go somewhat beyond, 250 000 kW in rating. Some "units" (so-called) will have ratings up to a million kilowatts. Very large units are usually 2 separate single-shaft turbine-generator sets with one or two turbines on each shaft. One turbine takes steam at high pressure and the others at intermediate or low pressure.

Direct-current generators are built with their dc magnetic poles on the stator. Armature conductors on the rotor have ac voltages induced in them as they are rotated; the same principle of flux cutting holds as before. An automatic mechanical switching device, called a commutator, is placed on the shaft. It carries fixed brushes, and with its many insulated copper bars connected to the armature coils, it inverts every other alternation of the voltage to give unidirectional, or dc, voltage at the 2 armature terminals. It is the commutator that requires the rotor to be the armature so that coils and their switching arrangement always move exactly together. Direct-current generators are generally limited to several thousand kilowatts, and their application lies mainly in industrial plants.

Generators in stations of electric utility companies are driven by steam turbines, water wheels, or water turbines. The ratio of steam to hydro-power is 4 to 1. Industrial production of steam plus hydro is about one-twelfth that of utility steam alone. The installed generating capacity in this country is over 210 million kW, about one-third of the world total. The United States produces about four times the energy in kilowatt-hours as the rest of the world.

In addition to power generation by steam and hydro, electric power also is obtained from gasoline- and diesel-driven motor-generator sets; from batteries, fuel cells, and solar cells; by thermoelectricity and photoelectricity; and by wind motion. Most of these are described elsewhere in this volume. Power production by these

last methods is small compared with steam and water power. Windmills are used to charge batteries, but use of wave motion or tides has never proved feasible.

The only fuels of consequence used by steam plants are coal, oil, and gas. Coal has predominated in the eastern part of the United States, with oil and natural gas used in the western states. Burners for oil or gas plants may be adaptable for either type of fuel, or they can be interchanged quickly. In some instances, provision is also made for coal burning.

Nuclear steam plants have now demonstrated safety, economy, reliability, and excellent performance. They are competitive with conventional plants and indicate better capabilities. They conserve natural resources, give less air pollution, and in small sizes have applications not possible with other forms. There are now over 1 million kW installed in civilian reactor plants, and by 1980, 40 million kW are expected, about 17 per cent of the total required capacity in the United States. Expansion here and in Europe is rapidly advancing, and plans indicate 1 million kW in a single plant.

Geothermal production of electric power uses natural steam obtained from the earth through steam wells and piped to turbines. Italy produces about one-third of a million kW in this manner and New Zealand has slightly less installed capacity of this kind. The only U.S. installation is about 30 000 kW on the West Coast. Geothermal power is limited. Temperatures and pressures are low, but there is a lower capital investment and absence of fuel cost. A serious problem lies in elimination of contamination in the steam.

Major problems today include improvement of over-all characteristics and economy of existing apparatus, development of materials to withstand increasing temperatures and stresses; the disposal of combustion products and radioactive wastes, and finding new and enlarged power applications. Some envision the elimination of the conventional plant with its rotating machinery, associated equipment, noise, and maintenance.

Among new methods currently studied for power generation are the magnetohydrodynamic (MHD) generator, fuel cell, thermionic converter, thermoelectric generator, and fusion reactor. None are yet practical and economic for a utility company even though there have been a few minor applications. Of this group, the first appears to be most promising.

The limited efficiency of steam turbines imposed by the thermodynamic properties of steam has stimulated the development of methods to convert heat directly into electricity. The MHD generator is one in which a thermally ionized gas is forced at high temperature, pressure, and velocity through a duct situated in a transverse magnetic field. An induced voltage appears in the third mutually perpendicular direction (the Hall effect), and this voltage may be tapped by electrodes within the duct (see MAGNETO-FLUID-MECHANICS).

If the exhaust gas from the MHD generator is used to heat steam for a conventional generator, a

larger portion of the thermal spectrum will be utilized and the system efficiency may be raised from the present 40 per cent to possibly 50 or 55 per cent. Heat for the system may come from the use of fossil fuel or nuclear reactors.

ELECTRIC PROPULSION

Electric propulsion is a form of rocket propulsion in which electric power, generated on board the propelled vehicle, is used to eject propellant rearward at high velocity to produce thrust. Electric propulsion systems can be considered to be made up of two major components: (1) the *electric power generation system*, which converts power from a basic power source (such as a nuclear reactor or the sun) into electric power, and (2) the *thruster*, which uses this electric power to produce thrust by ejecting the propellant.

The primary potential advantage of electric rockets over chemical rockets or solid-core nuclear rockets is that much higher propellant ejection velocities can be attained. Higher ejection velocities, in accordance with Newton's law, produce higher thrust per unit mass of propellant, so that the total mass of propellant needed for space missions can be greatly reduced. The mass of the required electric power generation equipment is appreciable, however, so that some of the saving in propellant mass is offset by the mass of the power generation system. The net mass saving possible using electric propulsion, therefore depends strongly on the difficulty and duration of the mission as well as on the performance parameters of the system.

One of the most important of these performance parameters is the propulsion-system specific mass α , which is defined as

$$\alpha = \frac{m_{\text{ps}}}{P_j} \frac{kg}{kW} \quad (1)$$

where m_{ps} is the total propulsion system mass (in kilograms) and P_j is the jet power produced (in kilowatts). If this parameter is less than about 15 kg/kW, electric propulsion systems can be employed to advantage over nuclear or chemical rockets for most unmanned interplanetary exploration missions. For such missions, typical required power levels range from several hundred kilowatts to a megawatt, to propel vehicles having

initial mass in earth orbit in the range of 10 000 to 100 000 kg.

If α is less than about 5 kg/kW, electric propulsion is superior to nuclear rockets, with regard to required initial weight and trip time, for manned expeditions to the near planets.¹ For these missions, power levels of several megawatts will be needed for vehicle weights (in orbit) of the range of 100 000 to 1 000 000 kg. In other possible applications, such as providing small amounts of thrust for attitude control or orbit control of satellites, the specific mass is less important, since the required electric power is small and can usually be obtained from the power supply used by the other on-board equipment.

Most of the mass of an electric propulsion system resides in the electric power generation system; however, the performance of the other major component, the thruster, is of equal importance in determining the over-all specific mass. The most important parameter for the thruster is the efficiency η with which the electric power is converted into jet power. If this efficiency is low, the required electric power, and therefore the power-plant mass, is correspondingly high.

Another important parameter for the thruster (as for all rockets) is the specific impulse I . This parameter is defined as the thrust F produced per unit weight flow of propellant:

$$I = \frac{F}{\dot{m}_p g_0} \quad \text{sec} \quad (2)$$

where \dot{m}_p is the mass flow rate of propellant and g_0 is the acceleration of gravity at the earth's surface (9.8 m/sec²), which relates mass to weight. The relation of thrust, specific impulse, and propellant ejection velocity is

$$F = \dot{m}_p g_0 I = \dot{m}_p v_j \quad \text{newtons} \quad (3)$$

where v_j is the mean propellant ejection velocity (more commonly called *effective jet velocity*). The first and last terms in Eq. (3) express Newton's law that force is equal to the time rate of change of momentum. The last two terms show that specific impulse is directly proportional to effective jet velocity.

The *jet power* is the time rate of change of jet kinetic energy, or

$$P_j = \frac{1}{2} \dot{m}_p v_j^2 = \frac{1}{2} F v_j = \frac{1}{2} g_0 I F \quad \text{newton-m/sec}$$

or, in kilowatts,

$$P_j = \frac{g_0 I F}{2000} \quad \text{kW} \quad (4)$$

For constant thrust and jet velocity, the total propellant mass m_p needed for a mission can be written [from Eq. (3)] as

$$m_p = \frac{F t}{g_0 I} \quad \text{kg} \quad (5)$$

where t is the total propulsion time and $F t$ is the total impulse required for the mission. From

Eq. (1) and (4), the propulsion system mass can be written:

$$m_{ps} = \alpha P_j = \frac{\alpha g_0 I F}{2000} \quad \text{kg} \quad (6)$$

These equations show that, although propellant mass can be reduced indefinitely by increasing the specific impulse [Eq. (5)], the power required (and therefore the power-plant mass) is increased when this is done [Eq. (6)]. It is, therefore, desirable to use that value of specific impulse for which the *sum* of the masses of propellant and propulsion system is lowest. This optimum specific impulse will yield the least total mass for the mission, or the highest payload mass, for a given total mass. For lunar and interplanetary missions and for specific weights likely to be obtained, calculations show that the optimum specific impulses range from about 1500 to 15 000 seconds (corresponding to jet velocities of about 15 to 150 km/sec). These specific impulses compare with values of about 450 seconds that are typical for high-energy chemical rockets and about 900 seconds that may be possible with solid-core nuclear rockets.

Another characteristic feature of electric propulsion systems is the very low thrust generated in comparison with chemical or nuclear rockets. This can be seen from Eq. (6) which can be written:

$$\frac{F}{m_{ps} g_0} = \frac{2000}{\alpha I g_0^2} \quad (7)$$

For a specific weight α of 10 kg/kW, and a specific impulse I of 5000 seconds, Eq. (7) yields a thrust-to-weight ratio of about 4×10^{-4} . This very low value results partly from the higher specific impulse typical of electric rockets, but mostly from the specific weight, which is of the order of 1000 or more times higher than that obtainable with solid-core nuclear rockets or chemical rockets. The low thrust-weight ratio means that electric propulsion systems cannot be used for launching from planetary surfaces. They are best suited for propelling vehicles between orbits about the planets or between orbits about the earth and the moon.

Because the thrust-weight ratio is so low, electric rockets must operate for much longer periods of time (of the order of 1000 times longer) than chemical or nuclear rockets to produce the same total impulse. Typically, for interplanetary missions to the near and far planets, these required operating times range from many months to several years. The removal of limitations on jet velocity, therefore, is obtained at the expense of greatly increased propulsion system weight and required operating lifetime.

Power Generation Systems. The need for low specific weight dominates the selection of suitable methods for generating electric power for primary propulsion of space vehicles. The requirement that power be generated with very little consumption of mass dictates that either nuclear or solar energy must be used as the basic energy source.

Among the possible methods of converting this energy into electric power, the most direct are photovoltaic solar cells and radioisotope cells. Considerable progress has been made in reducing the thickness, and hence the weight of photovoltaic solar cells;² eventual achievement of a specific mass near 5 kg/kW appears possible. A lightweight radioisotope cell, in the range of 1 kg/kW, has been proposed and analyzed³ but not yet demonstrated. This cell is basically a very high-voltage, low-current device, which converts a large fraction of the kinetic energy of the isotope decay particles directly into electric power. This system matches the requirements with respect to voltage and current, of colloidal-particle thrusters (see "Thrusters," p. 187).

Somewhat less direct in energy conversion are systems that use thermionic cells

$$\begin{pmatrix} \text{nuclear} & \text{--} & \text{heat} & \text{--} & \text{electricity} \\ \text{solar} & & & & \end{pmatrix}$$

A nuclear reactor or solar concentrator is used to heat a suitable material (such as tungsten) to temperatures high enough to produce thermal emission of electrons. These electrons traverse a gap to a cooled collector electrode, thereby producing electric power at a potential of the order of 1 volt. Many thousands of these thermionic cells must be connected in series-parallel combinations to achieve the required power levels and voltages. Also, to produce useful power densities, emitter temperatures must be in the range 1500 to 2000 K. Conversion efficiencies (heat into electric power) of 15 to 20 per cent are possible. The remaining 80 to 85 per cent of the thermal power must be radiated into space. The collector electrodes, where this waste heat appears, are, in the lighter-weight configurations, buried within the nuclear reactor or the heat absorber of the solar collector, so that a heat-transfer fluid must be pumped past the collector to pick up the waste heat and carry it to a radiator. In order that the radiator be of adequately low size and weight, it must operate at temperatures of about 1000 K or

higher. Analyses for a complete nuclear thermionic system yield specific masses of the order of 4 to 10 kg/kW, but numerous severe performance, design, and engineering problems remain to be solved before such systems can be developed to mission status.¹

Still more indirect, in the conversion of energy, are the turbopropeller systems

$$\begin{pmatrix} \text{solar} & \text{--} & \text{heat} & \text{--} & \text{mechanical} & \text{--} & \text{electric} \\ \text{nuclear} & & & & & & \end{pmatrix}$$

For these, as well as the thermionic systems, the nuclear reactor appears to be a better basic energy source than the sun, because it provides a more compact and versatile system, suitable for operation in shaded regions and at any distance from the sun.

A nuclear turbopropeller system for electric propulsion (as illustrated in Fig. 1) is basically a lightweight adaptation to space conditions of ground-based nuclear power stations.⁵ The chief differences result (as for the thermionic systems) from the lack of means other than radiation to eliminate the waste heat resulting from inescapable conversion inefficiencies. To produce specific weight below 10 kg/kW the waste-heat radiator must operate at temperature above 900 K, which in turn requires that the nuclear reactor operate at temperatures in excess of 1200 K.

The most suitable working fluid, at these temperatures, is potassium if a liquid-vapor thermodynamic cycle (Rankine cycle) is used. In a single-loop version of this cycle, the liquid metal is vaporized in the nuclear reactor; the resulting vapor drives the turbine, which in turn drives the generator to produce electric power. The vapor passes from the turbine through the radiator, where it is recondensed, and the liquid is then recirculated through the reactor. A major problem is to develop materials with adequate corrosion resistance during long periods of high-temperature operation with alkali liquid metals. As illustrated in Fig. 1, the radiator is the largest and heaviest part of the system. The necessarily

FIG. 1. Conceptual design of space vehicle for manned Mars mission. Nuclear turbopropeller propulsion system.

large exposed area is vulnerable to micrometeoroid penetration. Until more information is available on the flux and distribution of these particles in space, the precise wall thickness (and weight) needed to provide negligible penetration probability cannot be accurately estimated. Current evidence, however, suggests that the micrometeoroid hazard is less severe than previously estimated. Of all power generating systems suitable for electric propulsion, the Rankine-cycle, liquid-metal nuclear turboelectric system is nearest the stage of development for space missions.

Thrusters. A large number of methods are possible to eject propellant by use of electric power. These are generally divided into three categories: (1) *electrostatic thrusters*, in which atoms (or heavier particles) are electrically charged and then accelerated rearward by means of an electrostatic field; (2) *plasma thrusters*, in which the propellant is made into an electrically conducting gas and accelerated rearward by application of electromagnetic forces; (3) *electro-thermal thrusters*, which use the electric power to heat the propellant, and then accelerate it rearward by thermal expansion through a nozzle.

Electrostatic thrusters that accelerate atomic ions (ion rockets) have received the most research and development attention, as a result of early demonstrations of good efficiencies in the range of specific impulses needed for major space missions. Typical of these ion rockets is an electron-bombardment thruster (such as that shown in Fig. 2) which uses mercury vapor as propellant.⁶ The propellant atoms are ionized by collision with electrons emitted by the cathode

and attracted toward the anode. A weak axial magnetic field is maintained in the ionization chamber to make the electrons spiral around on their way to the anode, thereby increasing their path length and their probability of colliding with propellant atoms. The resulting positive ions are extracted through a screen grid by means of an accelerating grid that is maintained at the proper voltage difference (usually several thousand volts) to produce the desired ejection velocity (specific impulse). A second electron emitter (not shown) is placed adjacent to the ion beam, downstream of the accelerator, to neutralize both the ion space charge and the net current leaving the thruster. Experimental efficiencies in converting electric power into jet power range from 60 to 80 per cent at specific impulses in the range 4000 to 9000 seconds. Thrusters in sizes up to 50 cm in diameter, with jet powers near 30 kW have been successfully operated.²

Other ion thrusters, using contact ionization of cesium atoms on hot tungsten to produce the ions (rather than electron bombardment), have achieved somewhat lower performance. In these thrusters, cesium vapor is passed through porous tungsten, which must be heated to about 1500 K to evaporate enough cesium ions from the ionizer surface. The high work function of tungsten and the low ionization potential of cesium make these two substances the most promising for contact ionization thrusters.

Atomic-ion thrusters tend to become less efficient at low ejection velocities (low specific impulse), because a certain fixed amount of energy is needed to ionize the propellant atoms. As the ejection velocity decreases, the jet power

FIG. 2. Cutaway photograph of electron-bombardment ion thruster. With about 1 kW of power, this unit produces a thrust of 2.5 grams at a specific impulse of 5000 sec.

approaches the power required for ionization, and the efficiency decreases. A possible way to increase the efficiency is to increase the mass of each charged particle so that its kinetic energy, at a given jet velocity, is higher. This approach leads to use of colloidal particles in place of atomic ions. Because of the much higher mass per unit charge, voltages in the hundreds of kilovolts are needed to produce the desired jet velocities. Research is underway to find ways of efficiently generating, charging, and accelerating such particles.⁸

Although the efficiencies attainable with electrostatic thrusters are high, there remains a limitation which, although not crucial, is undesirable, namely, a low thrust (or power) per unit beam area, due to limitations on ion beam current density. These limitations result from two sources: (1) space charge and (2) accelerator electrode erosion. The space-charge limited current is determined by the accelerating voltage and the distance between accelerator electrode and ion source. The voltage, in turn, is approximately fixed by the desired specific impulse, and the accelerator spacing is limited by electrical breakdown and thermal warping. The erosion limitation appears to be even more restrictive on thrust per unit area than space charge.⁸ As the current density is increased, there is greater impingement of ions on the accelerator electrode. For an accelerator lifetime of the order of 1 year, estimates indicate a limit for thrust per unit beam area of about 2 newtons (0.2 kg) per square meter (about 50 kW/m²) at a specific impulse of 5000 seconds. Higher values are allowable as specific impulse increases.

Plasma thrusters, which operate on the principle of accelerating an electrically conducting but neutral gas (plasma), are not subject to the space-charge limitation. Furthermore, some require no electrode contact with the propellant stream. Consequently, a higher thrust per unit area, with adequate operating lifetime, may be possible with plasma thrusters than with ion thrusters. A variety of plasma thrusters are currently being investigated,⁹ but so far the efficiencies have been much lower than those of the ion thrusters.

Electrothermal thrusters are primarily of two types—the electric-arc jet and the electrically powered hydrogen heater (also called resistojets). The hydrogen heater is limited to specific impulses less than about 1000 seconds, because of the limitation on the wall temperature of the heater. High efficiencies, however, have been achieved.¹⁰ The arc jet, which heats the propellant by means of continuous electric discharge as the propellant flows by, can achieve somewhat higher specific impulses (up to about 2000 seconds), but the efficiency is generally less than 50 per cent, due to losses involved in dissociation and ionization of the propellant atoms, and losses to the walls of the arc chamber and nozzle. Because of the lower specific impulse range, electrothermal thrusters are not useful for interplanetary missions, but may be used for more limited applica-

tions such as satellite orientation control and orbit correction.

Some hybrid thrusters, which are combinations of the three major categories, have also been studied. One of these is an electrostatic ion accelerator in which the electrons are held by a magnetic field in the accelerating region while the ions pass through.⁹ In this device, the space-charge limitation on ion current density is removed, but as yet the efficiency has not been good. Another device is an arc-jet that is operated at very low gas density but high arc current. In this device, in addition to the heating, there is an electromagnetic acceleration due to interaction of the high arc current with its own, or an externally imposed, magnetic field. In this way, specific impulses of as much as 12 000 seconds have been attained, with efficiencies that are high, but not as high as those obtained with atomic-ion thrusters.¹¹

History and Status. The possibility of reducing propellant consumption by ejecting the propellant electrically at high velocities was recognized by early space flight and rocket pioneers, such as Goddard¹³ and Oberth,¹² but the practical feasibility of such propulsion systems was not demonstrated. With the advent of nuclear-electric power and large rockets during and after World War II, more interest in electric propulsion was aroused, and between 1946 and 1956, a number of preliminary analyses of nuclear and solar electric systems were published.^{14,15} The use of cesium-tungsten electrostatic thrusters was first proposed by Stuhlinger,¹⁵ and early experimental work in the United States, beginning in 1957, was concentrated on this approach.¹⁶⁻¹⁹

A systematic, comparative study of the applicability of electric, nuclear, and chemical propulsion to future space missions, together with an engineering study of large electric power systems for space use, were completed in 1957.²⁰ These and similar studies led to the initiation of major research programs in electric propulsion and power generation at U.S. government and industrial laboratories. Since, 1957, under the stimulus of a major national space program, these studies have expanded greatly and have covered a wide spectrum of promising methods.

At the same time, many low-thrust trajectory studies and mission analyses²¹⁻²⁵ have further clarified the role of electric propulsion in future space missions.

Numerous facilities for testing electric thrusters and components of power generation systems are now available. Vacuum tanks at the NASA Lewis Research Center, for example, permit testing of complete electric thruster systems up to the megawatt power range, and facilities under construction will permit vacuum testing of complete nuclear-electric power and propulsion systems in the sizes needed for unmanned and manned interplanetary travel. If the current research and development programs prove successful, electric propulsion systems suitable for unmanned interplanetary exploration could be

available in the early or middle 1970's, and systems for manned interplanetary exploration of the near planets by the late 1970's. The major problems are those of producing systems with adequate operating lifetime and reliability while maintaining low weight and high efficiency.

ELECTRICAL DISCHARGES IN GASES

Motion of Slow Electrons in Gases. Suppose that a swarm of electrons traverses a gas in which a uniform electric field X exists. In general the distribution of energy among the electrons will depend on the distance x which they have traveled in the field. However, provided x is sufficiently large, the energy distribution attains a steady value independent of x . In this steady state, the average rate of supply of energy to an electron from the field is equal to the average rate of loss of energy in collisions with gas molecules.

Many important quantities in this subject are related to $eX\lambda$, the energy gained by an electron of charge e in traveling the mean distance λ between two successive collisions with gas molecules. Since λ is inversely proportional to the gas density, the above quantity can be expressed in the form $X P_0$, where P_0 is the gas pressure reduced to some standard temperature.

The mean energy of an electron in the swarm, $\bar{\epsilon}$, is a function only of $X P_0$ for a particular gas. Figure 1 shows the form of this variation for a monatomic gas (He) and a diatomic gas (N₂). Here $k = \bar{\epsilon}/\bar{\epsilon}_k$, where $\bar{\epsilon}_k$ is the mean kinetic energy of a gas molecule at 15°C (0.037 eV). It is seen that the mean electron energy greatly

FIG. 1. Mean electron energy as a function of X/P_0 for He and N_2 .

exceeds the mean energy of a gas molecule even when X/P_0 is small. This is due to the inefficient energy exchange in collisions between electrons and gas molecules. If the collisions are elastic, it is readily shown that $\bar{\epsilon}$, the mean fractional energy lost by an electron in a collision, is $\sim 2m/M$ where m is electron mass and M is molecular mass. Clearly $f_e \ll 1$. At a given X/P_0 , $\bar{\epsilon}$ is generally lower in polyatomic than in monatomic gases. Owing to the possibility of inelastic collisions involving vibrational or rotational excitation of the molecule, $f \gg 2m/M$ in the former case. In the latter case, only electronic excitation of the atom can occur and this requires much higher energies in general.

In addition to their random motion, the electrons must obviously possess a superimposed drift motion in the direction of the applied field. Figure 2 shows the variation of the drift velocity W_e with X/P_0 ; normally W_e is small compared to the mean random speed of the electrons.

FIG. 2. Electron drift velocity as a function of X/P_0 for He, A and N_2 .

Ionization by Electron Collision. When the energy of an electron exceeds a certain critical value ϵ_i , ionization can occur at a collision with a gas molecule. As X/P_0 , and hence $\bar{\epsilon}$, is increased, an increasing fraction of electrons in the swarm will have energies exceeding ϵ_i . The size of the electron swarm will then increase with the distance x traveled in the field direction.

This growth is most conveniently studied under conditions where $\bar{\epsilon}$ is kept constant. This can be done by releasing electrons from the cathode

of a plane-parallel system and varying the electrode gap d and potential difference V in such a way that the electric field $X (= V/d)$ is fixed. It is then found that the electron current at the anode, i , increases exponentially with d or V . That is

$$i = i_0 \exp(\eta V) \quad (1)$$

where i_0 is the electron current released from the cathode and η is the electron ionization coefficient: this is defined as the average number of ionizing collisions made by an electron in moving through a 1-volt potential difference. η is also a function only of X/P_0 for a given gas (Fig. 3).

FIG. 3. Electron ionization coefficient as a function of X/P_0 for Air, Ne, A and $Ne + 10^{-2}\% A$.

It is important to note that the curve of η against X/P_0 passes through a maximum. The decrease in η at low X/P_0 is due to the increasing importance of excitation compared with ionization as X/P_0 decreases; since the excitation energy losses are larger in polyatomic than in monatomic gases, as remarked earlier, the decrease in η occurs more rapidly in air than in neon. The decrease in η at high X/P_0 (300 volts $\text{cm}^{-1} \text{ torr}^{-1}$), where excitation losses are comparatively unimportant, is due to the fact that an increasingly large fraction of the energy supplied from the field is used in maintaining the kinetic energy of the swarm.

The curve for the gas mixture $Ne + 10^{-2}\%$ per cent A is of great interest. Since the excitation potential of the most important metastable state of Ne (16.5 volts) exceeds the ionization potential of A (15.8 volts), the process $Ne^* + A \rightarrow Ne + A^+ + e$ can occur. This reaction has a very high probability, of the order unity per collision, and causes a great increase in η at low X/P_0 , above the value for pure neon, since the effective excitation energy losses are now considerably reduced. The double maximum in the curve of η vs X/P_0 arises from the fact that the direct and indirect ionization processes have their maximum efficiencies at different X/P_0 values (~ 70 and 2 volts $\text{cm}^{-1} \text{ torr}^{-1}$, respectively).

Secondary Ionization Processes. It is found that Eq. (1) no longer holds at larger values of

V_s ; i now increases more rapidly leading ultimately to spark breakdown. This is due to the occurrence of secondary ionization processes, in addition to ionization by collision between electrons and gas molecules. In general, the most important secondary process is the release of electrons from the cathode surface. If various simplifying assumptions are made, it can be shown that the ionization current is now given by:

$$i = \frac{i_0 \exp(\eta V)}{1 - \gamma[\exp(\eta V) - 1]} \quad (2)$$

where γ is a generalized secondary ionization coefficient. This is defined as the probability of a secondary electron being released from the cathode per positive ion arriving at the cathode. Included in γ are contributions to the secondary emission arising from radiation quanta and metastable molecules.

Since γ depends largely on the mean energies of the electrons and ions, it is, like η , a function only of X/P_0 though the function now depends on the nature of the cathode as well as on the gas.

Spark Breakdown. It is clear from the above equation that the ionization current tends to become very large as the potential difference across the gap approaches the value V_s given by:

$$\eta V_s = \log \left(1 + \frac{1}{\gamma} \right) \quad (3)$$

This is the condition for spark breakdown and can be best explained in the following manner.

Suppose that a primary electron current i_0 is released from the cathode when $V = V_s$. The electron current reaching the anode is then $i_0 \exp(\eta V_s)$. Hence, the positive ion current reaching the cathode due to the current i_0 is $i_0[\exp(\eta V_s) - 1]$. This will give rise to a secondary electron current of value $\gamma i_0[\exp(\eta V_s) - 1]$. If V_s is given by Eq. (3), then $\gamma[\exp(\eta V_s) - 1] = 1$ and the secondary current is equal to the original primary current i_0 . Hence it is clear that the process can continue even if the initiating current ceases. When V is less than V_s , however, the discharge current i is proportional to i_0 [Eq. (2)]. Thus $i = 0$ when $i_0 = 0$. It follows that $V = V_s$ marks the transition from a non-self-maintained to a self-maintained discharge. V_s is best defined as the potential difference required to maintain a small discharge current i when the primary current $i_0 = 0$. V_s is independent of i provided this is sufficiently small to avoid space charge distortion of the field.

Since η and γ are both functions only of X/P_0 and $X = V_s/d_s$ at breakdown, it follows from Eq. (3) that

$$V_s = F(P_0 d_s) \quad (4)$$

Thus, for a given gas and cathode material, the breakdown potential between large plane-parallel electrodes depends only on the product of the reduced gas pressure and electrode separation. This result, which is known as Paschen's law,

has been confirmed experimentally over a wide range of P_0 and d_s .

The variation of V_s with $P_0 d_s$ for a number of gases and cathode materials is shown in Fig. 4. It should be noted that the curves all exhibit a minimum; this corresponds to the maximum in the curve of η vs X/P_0 . It will be seen that the rise of V_s at high values of $P_0 d_s$ is most marked in air, less in pure Ne, and less still in the Ne + A mixture. This is readily understood by reference to the decrease in η at low X/P_0 ($= V_s/P_0 d_s$) in these gases (Fig. 3).

FIG. 4. Breakdown potential as a function of the product of the reduced gas pressure and electrode separation, $P_0 d_s$ for Air, Ne, and Ne + 0.0005% A with an iron cathode.

Time Lag of Spark Breakdown. If a potential difference $\geq V_s$ is suddenly applied to a discharge gap, a finite time elapses before the initial current i_0 has increased to a self-maintained discharge current $\sim 10^{-7}$ ampere/cm². This time lag consists of two parts. First of all, there is a statistical lag which arises from the fact that the primary and secondary ionization processes are both subject to statistical fluctuations. Thus, although $V = V_s$ where $\gamma[\exp(\eta V_s) - 1] = 1$ implies that on the average one electron leaving the cathode will give rise to one secondary electron, this may not happen in any particular case. Clearly the mean statistical lag t_s will decrease as the initial current is increased and it may be shown that

$$t_s = \frac{1}{PN_0} \quad (5)$$

where N_0 is the number of primary electrons leaving the cathode per second and P is the probability that any particular electron leads to breakdown. The latter quantity is zero at the sparking threshold V_s but increases rapidly for $V > V_s$. $P \approx 1$ provided $V > 1.25 V_s$.

The second component of the total time lag is the formative lag t_F . This can be regarded as the time that must elapse after the appearance of a suitable initiatory electron before the various ionization processes generate a self-maintained current of any given magnitude. This current can be chosen arbitrarily to specify breakdown of the gap and is generally taken to be $\sim 10^{-7}$ ampere/cm². Clearly t_F will depend on the relative importance of the various secondary mechanisms mentioned earlier; positive ion

transit times are typically $\sim 10^{-6}$ second, while the time lags involved in the contribution of radiation quanta and metastable molecules to γ are $\sim 10^{-8}$ and 10^{-3} second, respectively. The observed variation of t_F with overvoltage ΔV ($=V - V_*$) for various fixed values of X/P_0 in H_2 is shown in Fig. 5. Comparison with theory enables an estimate to be made of k , the relative contribution of photons at the cathode to the total γ . This ranges from 0.75 at $X/P_0 = 50$ to 0.50 at $X/P_0 = 300$ volts cm^{-1} torr $^{-1}$.

FIG. 5. Variation of formative time lag with overvoltage for various fixed values of X/P_0 in H_2 with copper electrodes

Glow Discharge. We have seen that any small current i can be maintained even in the absence of initiatory electrons when the potential difference between the electrodes reaches a value V_* given by Eq. (3). V_* is only independent of i when the latter is less than $\sim 1 \mu A$. At higher currents the space charge concentration becomes sufficient to cause X and hence η to vary across the gap, and ηV_* in Eq. (3) must be replaced by $\int \eta dV$. The static $V-i$ characteristic is normally negative since the field redistribution produced by the space charge effects increases the over-all ionization efficiency. Once breakdown has taken place, the current increases to a value determined by the impedance of the voltage supply.

If the current density is sufficiently small (< 0.1 ampere/cm 2), the cathode is not heated to a high enough temperature for thermionic emission to be a significant factor in the maintenance of the discharge. This regime is termed a glow discharge and the field variation across the gap in a long cylindrical tube is indicated in Fig. 6. We can distinguish five main regions here:

(1) The cathode fall, in which the field decreases from a high value at the cathode to approximately zero.

(2) The negative glow, in which ionization and excitation are due largely to fast electrons arriving from the cathode fall. The length of this region is normally controlled by the distance traveled by the electrons before their energy is reduced below the minimum required for excitation.

FIG. 6. Variation of axial field with distance from the cathode for a glow discharge in a long cylindrical tube.

(3) Faraday dark space. In many cases the ionization in the negative glow is so intense that the electron current here exceeds the total discharge current. A region is therefore required where electrons are lost by diffusion and not replenished by ionization; usually $X \leq 0$ here.

(4) The positive column, where X has a small constant value such that the corresponding electron energy distribution gives an ionization rate which just balances the loss of electrons and ions by radial diffusion to the walls.

(5) The anode fall, where X again increases.

Regions (1) and (2) are the most important regions of the discharge; the primary and secondary ionization by which the discharge is maintained take place here. The fall of potential across region (1), usually termed the cathode fall (V_*) is clearly an important parameter of the discharge.

It should be noted that the section extending from the negative glow to the anode has only a small field strength and small resultant space charge with $|n_i - n_e| \ll n_e$, where n_i and n_e are the ion and electron concentrations. This region is generally called a plasma. In many cases, the electrons here have a random motion which is large compared to their drift motion in the field direction. Our earlier discussion on electron swarms is valid here. On the other hand, the regions which occur near the cathode and the walls have a high field strength and resultant space charge with $n_i \gg n_e$. The electrons and ions behave here as a beam rather than as a swarm.

Ambipolar Diffusion. The radial diffusion of ions and electrons to the wall in the plasma region (4), above, does not occur at the same rate as when only one type of carrier is present. Clearly, the electrons will tend to diffuse to the walls much more rapidly than the ions leaving an excess of positive charge. A space charge field is set up which retards electrons and accelerates positive ions so that their effective diffusion rates are equalized. This process can be described in terms of the ambipolar diffusion coefficient D_a which is given approximately by:

$$D_a \doteq D_i \left[1 + \frac{T_e}{T_i} \right] \quad (6)$$

where D_i is the normal ion diffusion coefficient and T_e and T_i are the effective electron and ion temperatures, respectively.

Cathode Fall. When the current is sufficiently

small (≤ 10 mA for a cathode of area ~ 1 cm²), the discharge does not occupy the entire cathode area. The current density in the covered portion j_n is approximately constant, and the cathode fall of potential V_c is nearly independent of current and pressure. This is termed the normal cathode fall. The abnormal cathode fall occurs when $i > j_n S$, where S is the total cathode area. V_c now increases with current.

Arc and High Current Discharges. If i is increased sufficiently, a stage will eventually be reached where the cathode temperature is high enough for thermionic emission to be important. V_c now decreases with further increase in i (Fig. 7), and we are in the region of the arc discharge. The transition current clearly depends on the rate of loss of heat from the cathode and only has a definite value when the surface is uniform. In some arc discharges (e.g., Hg), the emission mechanism is probably not thermionic; these are not fully understood however.

FIG. 7 Variation of cathode fall of potential with current for discharge in A at 30 torr pressure with spherical tungsten electrodes, 1.8 mm diameter.

We have assumed hitherto that the current is always sufficiently low for the magnetic field produced by the current to play an unimportant role in the discharge mechanism. At high currents this is no longer true, and the interaction of the self-magnetic field of the discharge and the current produces forces on the ionized gas comparable to the other forces acting. The required currents increase with the gas pressure p ; at normal temperatures, $i \sim 10^3$ amperes and $p \sim 1$ torr are required. The force due to the magnetic field tends to constrict the discharge, and a column so constricted is said to be pinched. This pinch effect offers a possible method of confining the hot gas to a channel remote from the walls of the containing vessel. However, a major obstacle to the achievement of a steady pinched discharge is the inherent instability of such a channel to lateral perturbations. This causes the pinched column to leave the axis of the containing tube and take up a helical path in contact with the walls. Although a suitable arrangement of magnetic fields may help to stabilize the discharge, the prospect of continuous operation of a pinched discharge does not appear promising.

ELECTRICAL MEASUREMENTS

In an *electrical measurement*, one is concerned with the evaluation of an electrical quantity—resistance, capacitance, inductance, current, voltage, power, energy—or of a quantity or relationship that depends on some combination of them. The measurement means may be a ratio device, such as a potentiometer or bridge in which generally similar quantities are compared; or it may be an electromechanical system in which a force is developed to produce a displacement proportional to the electrical quantity to be measured. Electrical indicating instruments, such as ammeters, voltmeters and wattmeters, use this principle. In still other measuring systems, the heating effect of an electric current is utilized.

The basis of any meaningful electrical measurement must ultimately be the *National Reference Standards* maintained by the National Bureau of Standards in Washington, D.C. The magnitudes of these National Reference Standards are assigned in terms of *absolute* measurements in which certain electrical quantities are determined in terms of appropriate mechanical quantities—the electrical system of units being related to the metric system of mechanical units in such a way that both systems have identical units of power and energy.

Two *absolute* measurements are needed to assign values to the National Reference Standards. Historically, these have been: (1) an *ohm* determination and (2) an *ampere* determination. In the ohm determination, a resistance is compared to the reactance of an inductor or capacitor at a known frequency. The magnitude of the inductor or capacitor is calculated from its measured dimensions, and the resistance value is thus assigned in terms of the mechanical units of length and time—the meter and the second. In the ampere determination, the value of a current carried by two coils is measured in terms of the force with which the coils interact. The force between the coils is opposed by the force of gravity acting on a known mass, and the ampere is assigned in terms of the mechanical units of length, mass, and time—the meter, kilogram and second. When the ampere experiment is performed, the measured current is passed through

a resistor of known value, and the potential drop is used to assign the electromotive force of a *standard cell*.

The basic National Reference Standards, in terms of which the *legal* electrical units are maintained, are groups of 1-ohm resistors and of standard cells of the cadmium sulfate type—the “Weston” saturated cell—whose values are assigned by *absolute* measurement, and whose mean is assumed constant during the interval between absolute measurements. At the National Bureau of Standards, the national resistance standard consists of ten 1-ohm resistors, fully annealed and mounted strain-free out of contact with the air in sealed containers. The national voltage standard consists of 44 Weston cells maintained at 28°C. On the basis of present evidence (1964), it is believed likely that the difference between the *legal* ohm and the defined *absolute* ohm does not greatly exceed a part in a million. The difference between the maintained *legal* volt and the defined *absolute* volt may possibly be as much as 10 to 12 parts in a million.

The *voltage divider* is the basis of many precise measurement networks. In general, it consists of a group of resistors or impedors (using resistance, capacitance, inductance, or some combination of them). Its operating principle is as follows: When the series circuit is tapped at an intermediate point but no current is drawn from the tap, the ratio of the voltage between the tap point and one terminal of the divider to the voltage impressed across the whole divider equals the ratio of the tapped resistance, (or impedance) to the total resistance (or impedance) of the divider. Modern dc potentiometers operating on this principle achieve an accuracy of a few parts in a million in comparing direct voltages and, with appropriate range-extending voltage dividers, can be used to measure voltages up to 1500 volts with an accuracy—referred to the legal volt—of 10 parts in a million. Standard cells can be intercompared to 1 to 2 parts in 10^7 , using special potentiometers designed to eliminate or minimize parasitic voltages. Direct currents can also be measured to a few parts in a million with a potentiometer, by comparing the voltage drop that the current produces in a known resistance with a known reference voltage.

In any measurement network using voltage-divider techniques, a sensitive detector such as a galvanometer must be included in the circuit element containing the tap point to indicate the absence of current in this branch. Although a number of electronic detectors have been developed for dc measurements, which are rugged and convenient to use, the D'Arsonval galvanometer, operated to make optimum use of its design characteristics, is still the most sensitive detector of voltage unbalance in potentiometers and in the usual dc bridge networks. In fact, unbalance detection at the nanovolt level in circuits having resistances up to a few hundred ohms is quite possible with the D'Arsonval galvanometer. A galvanometer consists basically of a coil of wire suspended by very fine metallic

filaments—usually flat ribbons—in a radial magnetic field. Current in the coil introduced through the suspension filaments, interacts with the magnetic field to produce a torque tending to rotate the coil. The suspension stiffness opposes the coil rotation. A light beam, reflected from a mirror fixed to the moving system, indicates the magnitude of the rotation and hence the current in the coil. The light beam can be focused on a scale for direct observation, or may be shared by two differentially connected photocells whose output is supplied to a second galvanometer, producing a greatly amplified deflection. Such a photoamplifier system may be used to achieve nanovolt response in the detector system.

Two voltage dividers may be connected in parallel to the same voltage source to form a *bridge*. Equality of divider ratios—indicated by zero voltage difference at their tap points—permits the accurate comparison of impedances and generally is relatively insensitive to minor variations in the level of the supply voltage. The best known bridge for dc resistance determination is the Wheatstone network. It incorporates two dividers, one of which provides a known ratio, the other includes the unknown resistor and a known resistor with which it is compared. The Wheatstone bridge is used for resistors, usually of value greater than 1 ohm, which have only two terminals, i.e., whose potential and current connections coincide. A second network, the Kelvin bridge, is used for resistors (usually an ohm or less) which have four terminals, i.e., whose potential and current terminals are separated. Two known ratios of identical magnitude must be provided in addition to the “divider” which incorporates the unknown and reference resistors. By employing one or the other of these bridges, and using a direct substitution method, nominally equal resistors can be compared to a few parts in a million or better in the resistance range from 10^4 to 10^{-4} ohm; at the 1-ohm level the comparison can be made to a part in 10^7 .

The more general impedance bridge is usually a 4-arm network similar to the Wheatstone bridge—or a more complicated network which, by appropriate star-delta transformations, can be reduced to an equivalent 4-arm network—in which, by proper choice of components, inductances can be intercompared or measured in terms of a combination of capacitance and resistance, or capacitances can be intercompared or determined by a combination of inductance and resistance. The accuracy of such bridges is usually limited by the stability of the reference components and the other elements of the bridge, and by how well their values are known. Additional limits may be imposed by intercoupling between bridge elements or by their coupling to nearby objects or to ground. Such coupling may consist of an ambient magnetic field inducing a parasitic emf in an inductive bridge element or even in open loops formed by connectors between bridge elements, or by capacitance or leakage resistance between elements or to a neighboring

source of potential or to ground. Such effects can be reduced or eliminated by choice and arrangement of inductive elements to avoid inductive coupling and by the use of shields maintained at appropriate potentials, to eliminate the effects of stray capacitance and leakage resistance on the bridge balance. Thus, no statement of bridge capability is possible except in the context of the individual components and their arrangement. As an extreme example of state-of-art measurements, 10-pF, 3-terminal capacitors can be compared to a part in 10^8 , in a completely shielded bridge whose ratio arms are formed of closely coupled transformer windings.

Indicating instruments are commonly used to measure current, voltage, and power, and with special circuit arrangements or transducers, they can be used to indicate other electrical quantities—resistance, frequency, phase—or nonelectrical quantities such as speed, temperature, pressure, level of illumination—in fact any quantity for which an appropriate transducer can be devised that will convert the measurand into a usable electric signal.

Direct-current instruments are usually of the permanent-magnet moving coil type, sometimes called D'Arsonval-type instruments because their operating principle is identical with that of the D'Arsonval galvanometer. A coil, suspended or pivoted in a radial field between the polepieces of a permanent magnet, tends to rotate from the mechanical interaction between its current and the field of the magnet. The turning moment of the coil is opposed by spiral springs in the case of a pivoted coil (or by the suspensions in a taut-band construction), and the equilibrium position of the coil is indicated by a pointer attached to it and moving across the instrument scale, which is marked in units of the quantity being measured. In a milliammeter, the entire current may be taken by the moving coil; in an ammeter, where the current is too large for the coil and connecting springs, a parallel circuit or shunt carries the bulk of the current, and only a fraction of it is taken by the moving coil; in a voltmeter, a large series resistance (or multiplier) is used to limit the coil current, and the indicated voltage is the product of coil current by total resistance between the instrument terminals.

In a permanent-magnet moving-coil instrument, the direction of the torque reverses with the direction of current in the moving coil. Therefore, this arrangement cannot be used for alternating-current indication. An arrangement is required for which the direction of torque is independent of current direction. A number of such arrangements are possible, and a variety of types of ac ammeters and voltmeters are used.

(1) The *rectifier* instrument makes use of four semiconductor rectifier elements arranged in a square with the input across one diagonal and a permanent-magnet moving-coil instrument connected across the other diagonal, the rectifier elements being arranged with their direction of conduction such that current in the permanent-magnet moving-coil instrument is in the same

direction for either polarity at the input terminals. This arrangement can be used either for a voltmeter or for a low-range current meter (a milliammeter), but its use for a high-range current meter (ammeter) is generally impractical. The *average* value of current or voltage over a half cycle of the alternating current is indicated. Since usually one is concerned with the effective (rms) value of current or voltage, the scale is marked in terms of the rms quantity for a sine-wave input, and wave-form errors are present for a non-sinusoidal input. Use of this type of instrument is restricted to relatively low frequencies, such as those used for transmitting power or those in the low audio-frequency range.

(2) *Thermocouple* instruments utilize the heating effect of an electric current. A fine wire or thin-walled tube is heated by the current to be measured; a thermocouple is attached to the heater element, and the temperature rise produces an emf whose value is indicated on a low-range permanent-magnet moving-coil millivoltmeter. Since the rate of heat production (and the consequent temperature rise in the heater element) is proportional to the square of the current, the indication is of *effective* (rms) value and there is no wave-form error. This type of instrument may be used for current measurement (milliammeters and ammeters) from dc to the rf range (with some constructions to 200 megahertz or more) without serious frequency errors. As a voltmeter, the use of this instrument is usually restricted to audio frequencies but, with multipliers of special design having low distributed capacitance, the useful range of thermocouple voltmeters can be extended upwards to a megahertz or more.

(3) *Electronic* instruments are used as voltmeters over a wide frequency range, extending upwards in some instances to several hundred megahertz. A variety of circuit arrangements are used. In one common arrangement, the voltage to be measured is rectified, reduced to an appropriate level by means of an attenuator, and impressed on the grid of a vacuum tube to control plate current. The magnitude of the plate current is a function of the grid voltage and is read on a dc milliammeter whose scale is marked directly in volts. In this instance, the response is to the peak value of the impressed alternating voltage, although the scale is generally marked in terms of rms volts for a sine-wave input. Thus, a substantial wave-form error may be present if the impressed voltage is not sinusoidal. In other circuit arrangements, peak, average or even rms values may be directly indicated, and it is important to know the response law of the instrument so that appropriate allowance may be made for wave-form errors if the response is not truly rms. Vacuum-tube voltmeters are an important class of instruments because of their wide frequency range and because, generally, their input impedance is quite high. In many electronic voltmeter circuits the power required for operation and indication is supplied from an auxiliary

source, and negligible power is taken from the circuit whose voltage is measured.

(4) In *moving-iron* instruments, a soft-iron piece forms the moving element. It is immersed in the field of a coil that carries the current to be measured, and its motion in the field is such as to increase the inductance of the system with increasing coil current. Since the energy stored in the magnetic field can be written $E = \frac{1}{2} I^2 L$, where L is the inductance of the system, its derivative—the torque—is $T = \partial E / \partial \theta = \frac{1}{2} I^2 \partial L / \partial \theta$, and the system's response is proportional to I^2 ; the instrument indicates rms (effective) current or voltage. By suitably shaping and arranging fixed and movable irons in the field of the coil, the instrument scale can be made very nearly linear over as much as 80 per cent of its range. Alternatively, the upper range of the scale can be greatly compressed, and a small portion of the total range can be expanded to cover much of the scale. The latter arrangement is particularly appropriate in a voltmeter that is used to monitor a voltage which is nearly constant most of the time, e.g., a line voltage.

(5) *Electrodynamic* ammeters and voltmeters have both a fixed and a moving-coil system, each of which carries the current to be measured or a fraction of it. The interaction of their fields produces a torque proportional to the square of the current if the coils are connected in series (in a voltmeter), or proportional to the product of the fixed and moving-coil currents in a parallel arrangement (in an ammeter). Thus the scale indication is of rms (effective) voltage or current as in the moving-iron instrument. Here, however, eddy-current errors are much less, and electrodynamic instruments are generally useful over an extended range of power- and low audio-frequencies. In addition, the dc response can be substantially error-free, and electrodynamic instruments are used extensively as ac-dc transfer standards to determine the ac performance of other instruments which cannot be calibrated reliably on dc.

This transfer function is an important one, since the basic standards of resistance and emf, and the potentiometer techniques for accurately measuring current and voltage, are available only on direct current. This function of electrodynamic instruments—ac-dc transfer standards—is generally confined to frequencies below a kilohertz. Over a more extended frequency range—to 20 kilohertz or more—thermocouple elements with appropriate shunts and series resistors are used as current and voltage transfer standards.

Electrodynamic instruments are also used as wattmeters to measure power at low frequencies, generally below 1 kilohertz. For this purpose, the moving coil with an appropriate series resistance is connected across the supply lines as the voltage circuit of the wattmeter. The fixed coils are connected to carry the load current. The instrument torque is proportional to the product of the currents in the fixed and moving-coil systems at any instant, and is therefore proportional to the instantaneous product of line

voltage and load current. The time integral of this product over a cycle (divided by the period) is the average power in the load, and since the moving system cannot follow variations within so short a time interval, it takes up a position that indicates average power—in effect, it performs the required integration. Thermoelement arrangements have been used to a limited extent in some laboratories to measure power through the audio-frequency range, but such instruments are not available commercially. In the rf and microwave regions, the precise measurement of power is difficult. Arrangements are available in which the power output of a circuit is absorbed in a calorimeter or bolometer, and its magnitude indicated by temperature rise, resistance change, or voltage developed across a fixed resistance.

The range of current, voltage or power that can be measured directly with indicating instruments is practically limited to a few amperes, or a few hundred volts or watts. *Instrument transformers* are used at power frequencies to extend the range of measurement capability almost indefinitely. For example, *current transformers* rated at 10 000 amperes are used in some installations, as are *voltage transformers* rated at 350 000 volts. Instrument transformers, consisting of a primary and a secondary winding coupled by a magnetic core, are designed specifically to accurately reproduce the primary current (or voltage) on a reduced scale in the secondary circuit. They are quite different from power transformers in details of design and operation, although their basic operating principle is the same. The usual *current transformer*, designed for use with a 5-ampere ammeter, or to supply the current circuit of a wattmeter or watt-hour meter, is capable of delivering only a few watts to these instrument circuits, and generally operates under nearly short-circuit conditions with its magnetic circuit at very low flux density. The usual *voltage transformer*, designed for use with a 120-volt voltmeter, or to supply the voltage circuit of a wattmeter or watt-hour meter, also generally has a relatively low power rating and operates under nearly open-circuit conditions with its magnetic circuit approaching saturation. Instrument transformers of good design can be expected to have errors of only a few hundredths or at most tenths of a per cent when operated within their design limits.

ELECTRICITY

An isolated atom consists of a small nucleus, itself composed of protons and neutrons, surrounded by a cloud of electrons. The proton and the electron are the ultimate stable particles of electricity. Their charges are equal and opposite, the proton being regarded, by convention, as positive. A normal atom with its full complement of electrons is thus uncharged.

Electrostatic phenomena arise when bodies (or parts of bodies) have an excess of electrons or protons, a state usually produced by transferring electrons, e.g., by means of a battery or by rubbing two dissimilar materials together. Between two positively charged bodies (or two negatively charged ones) there is a repulsive force; between positively and negatively charged ones, an attractive force. The nature of these forces is subsumed in Coulomb's law*

$$\mathbf{F} = \frac{1}{4\pi\epsilon_0} \frac{Q_1 Q_2}{r^2} \mathbf{r}_1 \quad (1)$$

where \mathbf{F} is the force between two charges Q_1 and Q_2 carried on bodies very small compared with their separation r (i.e., between "point" charges); \mathbf{r}_1 is a unit vector along the line joining Q_1 and Q_2 , and indicates that the force is directed along that line; and ϵ_0 is a constant that depends on the units used and takes the value $1/(36\pi \cdot 10^9)$ for the mks system of units. The forces between extended distributions of charge can be calculated by adding together (vectorially) the forces between the very small elements of charge into which the charge distributions can be imagined to be divided.

We can speak of the *electric field* of force \mathbf{E} at a point due to a system of charges and define it by means of the force \mathbf{F} on a *small* test charge q placed at the point:

$$\mathbf{E} = \mathbf{F}/q \quad (2)$$

For a point charge Q , the field at a distance r from it is then

$$\mathbf{E} = Q\mathbf{r}_1/4\pi\epsilon_0 r^2 \quad (2a)$$

If we slowly move a small charge q a small distance $d\mathbf{x}$ in a field \mathbf{E} , the electric system does work *against* the force \mathbf{F} holding the small charge in place, so the work done *on* the electrical system *by* the force is

$$dW = \mathbf{F} \cdot d\mathbf{x} = -q\mathbf{E} \cdot d\mathbf{x} \quad (3)$$

We define *electric potential difference* dV by

$$dV = dW/q = -\mathbf{E} \cdot d\mathbf{x} \quad (4)$$

The *electric flux* through a small geometrical (not necessarily material) surface of size dA is $\mathbf{E} \cdot d\mathbf{A}$ where $d\mathbf{A}$ is the vector normal to the surface. Then from equation (2a) for a surface A enclosing a charge Q , we have

$$\begin{aligned} \int_V \epsilon_0 \mathbf{E} \cdot d\mathbf{A} &= \int_Q \int_A \frac{dQ \mathbf{r}_1 \cdot d\mathbf{A}}{4\pi r^2} \\ &= \frac{1}{4\pi} \int_Q \int_\omega dQ d\omega = Q \end{aligned} \quad (5)$$

where $d\omega = \mathbf{r}_1 \cdot d\mathbf{A}/r^2$ is the solid angle subtended by dA at the element of charge dQ .

* We consider only systems which do not include dielectrics. For such see DIELECTRIC THEORY.

This is Gauss' theorem, one often of great assistance in solving electrostatic problems, for which the most difficult part can be to obtain the distribution of the charge on a system of conductors (which cannot sustain an electric field unless an emf is present or energy continuously supplied). For example, consider two parallel conducting plates of area S , a small distance t apart. Then ignoring edge effects, by symmetry \mathbf{E} is constant between the plates and perpendicular to them. Applying Gauss' theorem to a small cylinder with one end of area a in the positively charged plate (so for this end $\mathbf{E} \cdot d\mathbf{A} = 0$) and the other between the plates, we have, by Gauss' theorem, since \mathbf{E} is parallel to the sides (and so $\mathbf{E} \cdot d\mathbf{A}$ zero for the sides),

$$\int \epsilon_0 \mathbf{E} \cdot d\mathbf{A} = \epsilon_0 E a = Qa/S.$$

Then from Eq. (4) the potential difference between the plates is $V = Et = Qt/\epsilon_0 S$ and so the CAPACITANCE of the plates, defined as $C = Q/V$, is $\epsilon_0 S/t$.

The laws of electrostatics underly many phenomena such as thunderstorms and the behavior of electrons in radio and cathode-ray tubes.

Current Electricity. If two bodies at different potentials are connected by a conductor, such as a metal wire in which there are free electrons, the electrons in the wire drift under the influence of the electric field. Such movement of electrical charges gives rise to further phenomena and we speak of an *electric current*. This we can define quantitatively as the rate at which charge is passing:

$$I = dQ/dt \quad (6)$$

The current may be one of electrons only, as in a metal, in semiconductors or in electron tubes; of positive nuclei, as in an isotope-separator; or of both positive and negative charges, as in the conduction by ions (atoms that have gained or lost an electron) in liquids or in gaseous electrical discharges. (see CONDUCTIVITY, ELECTRICAL; ELECTRIC DISCHARGES IN GASES). Note that *electrons* flowing in the *positive* direction give rise, by our convention of signs, to a *negative* current and that in a metal, semiconductor, or conducting liquid, the velocity at which the electrons or ions drift is quite slow, less than 1 cm/sec even for current densities in a metal as high as 10^4 amperes cm^{-2} . In vacuum devices, such as cathode-ray tubes, the speed of the electrons approaches that of light.

If a wire joins two electrostatic charges, the current lasts for a short time only, but it may be maintained by means of some source of energy, such as a battery, a generator, a thermocouple, or a solar photoelectric cell.

When a current I flows under the influence of a potential difference V , the moving charges—electrons in metals, ions in solutions—are impeded by collision with the atoms in the conducting metal or liquid. The charges give up to the atoms the energy they acquired as they moved in the electric field, and electrical power is converted into other forms, — for instance, into heat in the case

of a metal wire. From Eqs. (4) and (6), this power P is given by

$$P = \frac{dW}{dt} = \frac{d(VQ)}{dt} = V \frac{dQ}{dt} = VI \quad (7)$$

A metal wire at constant temperature (but not all conductors) obeys Ohm's law: that is, $V = RI$, where R is a constant for the wire known as its resistance (in ohms if V and I are in volts and amperes). In this case

$$P = RI^2 = V^2/R \quad (8)$$

and this is the rate at which heat is generated. The heat in most forms of electric heaters (including filament lamps) is generated in this way. (For an explanation of how current flows in more complicated circuits see "CIRCUITRY.")

Accompanying a current I there is always a magnetic field \mathbf{H} which shows itself by the force exerted between the current-carrying conductor and a magnet or another electric current. At a point P a distance a from a long, thin, straight wire carrying current I , the field \mathbf{H} is perpendicular to both the wire and the radius from the wire to P , so that the "lines of force" are circles concentric with the wire and perpendicular to it. The field is of magnitude

$$H = I/2\pi a \quad (9)$$

For a long cylindrical coil, $H = nI$, where n is the number of turns per unit length. In general, we have the relation that

$$\oint \mathbf{H} \cdot d\mathbf{s} = NI \quad (10)$$

where N is the total number of turns, each carrying current I , enclosed by the path s . This holds true whether or not the path traverses magnetic materials. Associated with the field \mathbf{H} , there is a magnetic flux density \mathbf{B} ,

$$\mathbf{B} = \mu_0 \mu_r \mathbf{H} \quad (11)$$

where μ_0 is a constant of value $4\pi \times 10^{-7}$ in mks units and μ_r is the relative permeability. μ_r is not necessarily a constant, but it has the value 1 for free space and is of the order of 1000 for magnetic materials.

The magnetic flux density satisfies Gauss' theorem [see Eq. (5)], but because magnetic poles cannot be isolated in the way electric charges can be, the theorem takes the form

$$\int_A \mathbf{B} \cdot d\mathbf{A} = 0 \quad (12)$$

where the integral is taken over the geometrical surface A . Equations (10), (11) and (12) are sufficient, in principle, for the calculation of the magnetic field of any steady current.

The force between a current I , traversing a short length $d\mathbf{l}$ in a magnetic field of flux density \mathbf{B} , and the field is

$$I d\mathbf{l} \times \mathbf{B} \quad (13)$$

so for a wire of length l in a field perpendicular to it, the force is lB perpendicular to both wire and field. The force between two long parallel wires in free space, each carrying a current I and distance a apart, is, from Eqs. (9) and (13),

$$F = 2 \times 10^{-7} I^2 l / a \quad \text{newtons/m} \quad (14)$$

For currents in the same direction it is an attraction. This equation defines the mks unit of current though that unit is *established* by means of the larger force between coils carrying a common current I , for which $F = KI^2$, where K is a factor that can be calculated accurately from the geometry of the coils. The force between a current-carrying coil and magnetic material, or another current, is the basis of many electrical instruments such as ammeters, of electric motors and of other electromechanical devices.

If we think of the current as consisting of electrons, or ions, of charge Q , moving with velocity \mathbf{v} along a wire or in a vacuum, these experience a force in a magnetic field \mathbf{B} given by

$$\mathbf{F} = Q\mathbf{v} \times \mathbf{B} \quad (15)$$

a relation that is required for the explanation of the behavior of electrons in a magnetic electron microscope, of ions in a mass spectrometer, and of cosmic rays in the earth's magnetic field. Further, if a wire, with its electrons free except in so far as they are confined to the wire, and a magnetic field \mathbf{B} are caused to move relative to one another with velocity \mathbf{v} , by virtue of Eq. (15) the electrons will suffer a force *along* the wire; an INDUCED ELECTROMOTIVE FORCE is set up. If the ends of the wire are connected by a conductor, a current will flow. This is the phenomenon of *electromagnetic induction* and the basis of equipment such as transformers and electric generators.

When an electric current changes rapidly, electromagnetic waves are radiated. If the current is an alternating one, the power radiated, for a current of given size, increases as the square of the frequency. Such waves, at frequencies of 100 kc/sec or more, are the basis of radio communication.

Though electrostatic phenomena are important—in radio tubes, for instance—current electricity is vital in the modern world. Small currents can be maintained by batteries and secondary cells, but the very large amounts of power used in a modern industrial state must be obtained mainly by electromagnetic machinery (see ELECTRIC POWER GENERATION), usually as ALTERNATING CURRENTS.

ELECTROACOUSTICS

Introduction. Electroacoustics is concerned with the principles (*transduction processes*) and devices (*transducers*) by which electrical energy may be converted into acoustic energy and vice versa. Consider the familiar electrodynamic transducer. A periodic electric current passing through a coil interacts with a steady radial magnetic flux causing the coil to vibrate. The coil in turn drives a diaphragm which radiates sound waves from one side. (The other side is usually enclosed to avoid cancellation of the acoustic output.) The entire process is *reversible* since sound waves striking the diaphragm set up a periodic variation in air pressure adjacent to the diaphragm causing it to vibrate. As the moving coil cuts the magnetic flux, an emf is generated which causes a current to flow when a load is connected to the coil terminals.

Many, but not all, types of transducer are similarly reversible. A reversible transducer may be made to perform sending and receiving functions successively in such a manner that an absolute sensitivity may be determined (*reciprocity* calibration).

The electrodynamic transducer may further be classified as *passive* since all of the energy appearing in the acoustic load is derived from the electrical input energy, and *linear* in the sense that there is a substantially linear relationship between the input and output variables (electric current and acoustic pressure in the present case).

Transduction Processes. *Irreversible Transducers.* These depend on a variety of special effects of which the best known is (a) the variation of surface contact electrical resistance with pressure (carbon microphone). Other effects are (b) the variation of bulk resistance with elastic strain (piezoresistance), (c) variation of transistor parameters with strain, (d) cooling effect of periodic air movement (hot wire microphone), (e) pressure wave generated by an electrical spark, (f) dependence of air pressure on level of corona discharge (ionophone).

Reversible Transducers. A important class of reversible transducer depends on relative movement of suitable components linked by an electric or magnetic field traversing a gap. Examples are (a) the electrodynamic transducer already described; (b) electrostatic depending on the relative movement of charged condenser plates; (c) magnetic or variable reluctance depending on relative movement of magnetic poles in a magnetic circuit linked with a fixed coil.

Other *reversible transducers* are dependent on dimensional changes connected with the state of magnetic or electric polarization of certain crystalline materials (piezomagnetism and piezoelectricity). Since strain may be longitudinal or

shear and since both strain and polarization are directional quantities, many possible relationships between strain and polarization exist. The behavior of an X-cut quartz disk may serve as an illustration. When such a disk is axially compressed, electric charges appear on the plane surfaces. Conversely, if a potential difference is established between the two surfaces, contraction or expansion occurs depending on the direction of the electric field. Other important single-crystal piezoelectric materials are ammonium dihydrogen phosphate (ADP) and Rochelle salt. During the past decade, polycrystalline ceramic materials based on barium titanate and lead zirconate titanate have replaced single-crystal materials in many applications. These materials are ferroelectric and, when prepolarized, exhibit piezoelectric behavior.

To date, only polycrystalline piezomagnetic materials (often termed magnetostrictive) have been found useful. Some are metals such as nickel and permendur. Others are ferrite ceramics [basic composition: $(\text{NiO})(\text{Fe}_2\text{O}_3)$] which have such a high electrical resistivity that eddy current losses are negligible making lamination unnecessary.

Electromechanical Coupling. Transducer performance is closely connected with the tightness of coupling between mechanical and electrical aspects. Consider a piezoelectric disk which is compressed by putting in *mechanical* energy W_m . The appearance of surface charges shows that *electrical* energy W_e is stored in the self capacitance and is available when an external circuit is connected to suitable electrodes. The ratio W_e/W_m (electromechanical coupling coefficient) sets a limit to the efficiency for a given bandwidth (frequency range). The coefficient may reach 70 per cent for lead zirconate titanate.

Transducer Design. Impedance matching is of primary importance in electroacoustics. It may be likened to the choice of gear ratio and wheel size in automobile design. Impedance matching is generally closely related to transducer parameters such as beam width of projected or received sound and frequency response, as well as efficiency. The many available matching techniques include (a) resonance, (b) horn systems (acoustic transformers), (c) lever systems (mechanical transformers). In the direct radiator electrodynamic loudspeaker, the diaphragm is made large enough to interact with the acoustic medium (air) and yet small enough in relation to the sound wavelength (at low frequencies, at least) to ensure uniform projection of sound over a wide angle. In the condenser loudspeaker, a large transducer area compensates for the weakness of electrostatic forces. In the underwater sonar projector, slabs of piezoelectric ceramic may be sandwiched between metal plates to form a resonant device which radiates a narrow beam of sound with high efficiency over a narrow frequency range.

Recent Advances. Discoveries in the solid-state field have already provided new piezoelectric

and piezomagnetic materials. Recently the interaction between free electrons and phonons in cadmium sulfide has provided a means of amplifying ultrasonic waves. The polarization voltage hitherto required in condenser transducers may now be replaced by a prepolarized plastic film which stores the required charge indefinitely. Finally, intense acoustic waves at frequencies up to 5000 Mc/sec have been generated by electrostrictive processes accompanying the passage of laser beams through liquids and solids.

ELECTROCHEMISTRY

Electrochemistry is that branch of science which deals with the interconversion of chemical and electrical energies, i.e., with chemical changes produced by electricity as in electrolysis or with the production of electricity by chemical action as in electric cells or batteries. The science of electrochemistry began about the turn of the eighteenth century. In 1796 Alessandro Volta observed that an electric current was produced if unlike metals separated by paper or hide moistened with water or a salt solution were brought into contact. Volta used the sensation of pain to detect the electric current. His observation was similar to that observed ten years earlier by Luigi Galvani who noted that a frog's leg could be made to twitch if copper and iron, attached respectively to a nerve and a muscle, were brought into contact.

In his original design Volta stacked couples of unlike metals one upon another in order to increase the intensity of the current. This arrangement became known as the "voltaic pile." He studied many metallic combinations and was able to arrange the metals in an "electromotive series" in which each metal was positive when connected to the one below it in the series.

Volta's pile was the precursor of modern batteries (see BATTERIES).

In 1800 William Nicholson and Anthony Carlisle decomposed water into hydrogen and oxygen by an electric current supplied by a voltaic pile. Whereas Volta had produced electricity from chemical action these experimenters reversed the process and utilized electricity to produce chemical changes. In 1807 Sir Humphry Davy discovered two new elements, potassium and sodium, by the electrolysis of the respective solid hydroxides, utilizing a voltaic pile as the source of electric power. These electrolytic processes were the forerunners of the many industrial electrolytic processes used today to obtain aluminum, chlorine, hydrogen, or oxygen, for example, or in the electroplating of metals such as silver or chromium.

Since in the interconversion of electrical and chemical energies, electrical energy flows to or from the system in which chemical changes take place, it is essential that the system be, in large part, conducting or consist of electrical conductors. These are of two general types—electronic and electrolytic—though some materials exhibit both types of conduction. Metals are the most common electronic conductors. Typical electrolytic conductors are molten salts and solutions of acids, bases, and salts.

A current of electricity in an electronic conductor is due to a stream of electrons, particles of subatomic size, and the current causes no net transfer of matter. The flow is, therefore, in a direction contrary to what is conventionally known as the "direction of the current." In electrolytic conductors, the carriers are charged particles of atomic or molecular size called *ions*, and under a potential gradient, a transfer of matter occurs.

An electrolytic solution contains an equivalent quantity of positively and negatively charged ions whereby electroneutrality prevails. Under a potential gradient, the positive and negative ions move in opposite directions with their own characteristic velocities and each accordingly carries a different fraction of the total current through any one solution. Each fraction is referred to as the ionic transference number. Furthermore, the velocity increases with temperature causing a corresponding increase in electrolytic conductivity. This characteristic is opposite to that observed for most electronic conductors which show less conductivity as their temperature is increased.

The concept that charged particles are responsible for the transport of electric charges through electrolytic solutions was accepted early in the history of electrochemistry. The existence of ions was first postulated by Michael Faraday in 1834; he called negative ions "anions" and positive ones "cations." In 1853, Hittorf showed that ions move with different velocities and exist as separate entities and not momentarily as believed by Faraday. In 1887, Svante Arrhenius postulated that solute molecules dissociated spontaneously into *free ions* having no influence on each other. However, it is known that ions

are subject to coulombic forces, and only at infinite dilution do ions behave ideally, i.e., independently of other ions in the solution. Ionization is influenced by the nature of the solvent and solute, the ion size, and solute-solvent interaction. The dielectric constant and viscosity of the solvent play dominant roles in conductivity. The higher the dielectric constant, the less are the electrostatic forces between ions and the greater is the conductivity. The higher the viscosity of the solvent, the greater are the frictional forces between ions and solvent molecules and the lower is the electrolytic conductivity.

In 1923 Debye and Hückel presented a theory which took into account the effect of coulombic forces between ions. They introduced the concept of the ion atmosphere, in which at some radial distance r from a central ion, there is, on a time average, an ionic cloud of opposite charge which sets up a potential field whose magnitude depends on the magnitude of r . This interionic attraction leads to two effects on the electrolytic conductivity. Under a potential gradient, an ion moves in a certain direction. However, the ion cloud, being of opposite sign will tend to move in the opposite direction, and because of its attraction for the central ion, will have a retarding effect on the ion velocity and thereby lead to a lowering in the electrolytic conductivity. On the other hand, the central ion will tend to pull the ion cloud with it to a new location. The ion atmosphere will adjust to its new location in time, but not instantaneously, and the delay results in a dissymmetry in the potential field around the ion. This also causes a lowering in the conductance of the solution. These effects become more pronounced as the concentration of the solution is increased; for dilute solutions, below about 0.1 molal, the equivalent conductance decreases with the square root of the concentration. For more concentrated solutions, the relation between conductivity and concentration is much more complex and depends more specifically on individual solute properties.

Interionic attraction in dilute solutions also leads to an effective ionic concentration or activity which is less than the stoichiometric value. The *activity* of an ion species is its thermodynamic concentration, i.e., the ion concentration corrected for the deviation from ideal behavior. For dilute solutions the activity of ions is less than one, for concentrated solutions it may be greater than one. It is the ionic activity that is used in expressing the variation of electrode potentials, and other electrochemical phenomena, with composition.

When electricity passes through a circuit consisting of both types of electrical conductors, a chemical reaction always occurs at their interface. These reactions are electrochemical. When electrons flow from the electrolytic conductor, oxidation occurs at the interface while reduction occurs if electrons flow in the opposite direction. These electronic-electrolytic interfaces are referred to as *electrodes*; those at which oxidation occurs are known as *anodes* and those at which

reduction occurs, as *cathodes*. An anode is also defined as that electrode by which "conventional" current enters an electrolytic solution, a cathode as that electrode by which "conventional" current leaves. Positive ions, for example, ions of hydrogen and the metals, are called *cations* while negative ions, for example, acid radicals and ions of nonmetals are called *anions*.

In 1833, Michael Faraday enunciated two laws of electrolysis which give the relation between chemical changes and the product of the current and time, i.e., the total charge (coulombs) passed through a solution. These laws are: (1) the amount of chemical change, e.g., chemical decomposition, dissolution, deposition, oxidation, or reduction, produced by an electric current is directly proportional to the quantity of electricity passed through the solution; (2) the amounts of different substances decomposed, dissolved, deposited, oxidized, or reduced are proportional to their chemical equivalent weights. A chemical equivalent weight of an element or a radical is given by the atomic or molecular weight of the element or radical divided by its valence; the valence used depends on the electrochemical reaction involved. The electric charge on an ion is equal to the electronic charge or some integral multiple of it. Accordingly, a univalent negative ion has a charge equal in magnitude and of the same sign as a single electron, and its chemical equivalent weight is equal to its atomic weight, if an element, or to its molecular weight, if a radical. A trivalent ion has $+3$ or -3 electronic charges, depending on whether it is a positive or a negative trivalent ion. For trivalent ions, then, the equivalent weight would be equal to its atomic weight, if an element, or to its molecular weight, if a radical, divided by three.

The quantity of electricity required to produce a gram-equivalent weight of chemical change is known as the *faraday*. A faraday corresponds, then, to an *Avogadro number of charges*. The most accurate determination of the faraday has been made by a silver-perchloric acid coulometer in which the amount of silver electrolytically dissolved in an aqueous solution of perchloric acid is measured. This method gives 96487 coulombs (or ampere-seconds) per gram-equivalent for the faraday or the unified C^{12} scale of atomic weights adopted in 1961 by the International Commission on Atomic Weights.

The *electrochemical equivalent* or, preferably, the *coulomb equivalent* of an element or radical is that weight in grams which is equivalent to one coulomb of electricity and is given by the gram-equivalent weight divided by the faraday (96487 coulombs per gram-equivalent); for example, the electrochemical equivalent of silver is given by $107.870/96487$ or 0.00111797 g/coulomb where 107.870 is the atomic weight of silver based on the unified C^{12} scale adopted in 1961. The electrochemical equivalents of other elements may be calculated in like fashion.

In electrolysis and in any electric cell or battery, there is an electromotive force (emf) or voltage across the terminals. This emf is expressed

in the practical unit, the volt, which is equal to the electromagnetic unit in the meter-kilogram-second system. In any one cell, the emf is the sum of the potentials of the two electrodes and of any liquid-junction potentials that may be present. Neither of the individual electrode potentials can be evaluated without reference to a chosen reference electrode of assigned value. For this purpose, the hydrogen electrode has been universally adopted and is arbitrarily assigned a zero potential for all temperatures when the hydrogen ion is at unit activity and the hydrogen gas is at atmospheric pressure. A hydrogen electrode consists of a stream of hydrogen gas bubbling over platinized platinum or gold foil and immersed in a solution containing hydrogen ions; the electrochemical reaction is: $1/2\text{H}_2(\text{gas}) \rightleftharpoons \text{H}^+(\text{solution}) + e$, where e represents the electron. The potential of the hydrogen electrode, E_{H} , as a function of hydrogen ion concentration and hydrogen-gas pressure is given by

$$E_{\text{H}} - E_{\text{H}}^0 = (RT/nF) \ln (a_{\text{H}^+} / p_{\text{H}_2}^{1/2}) \\ = E_{\text{H}}^0 - (RT/nF) \ln (c_{\text{H}^+} f_{\text{H}^+} / p_{\text{H}_2}^{1/2}),$$

where E_{H}^0 is the standard quantity assigned a value of zero, R is the gas constant, T the absolute temperature, n the number of equivalents, F the faraday, p_{H_2} the pressure of hydrogen, and a_{H^+} , c_{H^+} , and f_{H^+} , respectively, the activity, concentration, and activity coefficient of hydrogen ions. When a_{H^+} and $p_{\text{H}_2}^{1/2}$ equal one, $E_{\text{H}} = E_{\text{H}}^0$. For very dilute solutions below 0.01 molal f_{H^+} may be taken as unity without appreciable error.

The standard potentials, E^0 , of other electrodes are obtained by direct or indirect comparison with the hydrogen electrode. Values thus obtained at 25°C for some typical elements are listed in Table I.

The reducing power of the elements decreases on going down the column. These values are for the ions at unit activity, and reversible or thermodynamic values as a function of metal or radical concentration are given by equations similar to the one above. For the general reaction: $\text{M} \rightleftharpoons \text{M}^{n+} + ne$, the potential is given by $E_{\text{M}} = E_{\text{M}}^0 - (RT/nF) \ln a_{\text{M}^{n+}}$.

In electrolysis, at very low current densities, the potentials of the electrodes approximate in magnitude their reversible values and deviate somewhat from these values because of an IR drop in the solution and possible concentration polarization (the concentration at the electrode surface may differ from that in the bulk of the solution). Also for high current densities, especially for the generation of gases such as hydrogen, oxygen or chlorine, the voltage required exceeds the reversible voltage; the excess voltage is known as overvoltage, or overpotential for a single electrode, and arises from energy barriers at the electrode. Overpotential, in general, increases logarithmically with an increase in current density.

In addition to the above topics, it is frequently customary to include under electrochemistry: (1) processes for which the net reaction is physical transfer, e.g., concentration cells; (2) electrokinetic phenomena, e.g., electrophoresis, electroosmosis, streaming potential; (3) properties of electrolytic solutions if determined by electrochemical or other means, e.g., activity coefficients and hydrogen ion concentration; (4) processes in which electrical energy is first converted to heat which in turn causes a chemical reaction to occur that would not do so spontaneously at ordinary temperature. The first three are frequently considered a portion of physical chemistry, and the last one is a part of electrothermics or electrometallurgy.

The passage of electricity through gases is sometimes included under electrochemistry. However, in electrical discharges in gases, the principles are entirely different from what they are in the electrolysis of electrolytic solutions. Whereas in the latter, ionic dissociation occurs spontaneously as a result of forces between solvent and solute and without the application of an external field, for gases relatively high voltages must be applied to accelerate the electrons from the electrode to a velocity at which they can ionize the gas molecules they strike. In this case, the resulting chemical reaction taking place between ions, free radicals, and molecules occurs in the gas phase and not at the electrodes as in

TABLE I. SOME STANDARD ELECTRODE POTENTIALS AT 25°C

Electrode	Potential (V)	Electrode	Potential (V)
$\text{Li} \rightleftharpoons \text{Li}^+ + e$	-3.045	$\text{Cu} \rightleftharpoons \text{Cu}^{++} + 2e$	+0.337
$\text{Ca} \rightleftharpoons \text{Ca}^{++} + 2e$	-2.87	$\text{Cu} \rightleftharpoons \text{Cu}^+ + e$	+0.521
$\text{Na} \rightleftharpoons \text{Na}^+ + e$	-2.714	$2\text{I}^- \rightleftharpoons \text{I}_2 + 2e$	+0.536
$\text{Mg} \rightleftharpoons \text{Mg}^{++} + 2e$	-2.37	$2\text{Hg} \rightleftharpoons \text{Hg}_2^{++} + 2e$	+0.789

$\text{Ni} \rightleftharpoons \text{Ni}^{++} + 2e$	-0.250	$\text{Au} \rightleftharpoons \text{Au}^+ + e$	+1.68
$\text{H}_2 \rightleftharpoons 2\text{H}^+ + 2e$	0.000	$2\text{F}^- \rightleftharpoons \text{F}_2 + 2e$	+2.87

the electrolysis of solutions. Studies of the electrical conduction of gases, accordingly, are generally considered under the physics of gases.

Electrochemistry finds wide application. In addition to industrial electrolytic processes, electroplating, and the manufacture and use of batteries already mentioned, the principles of electrochemistry are used in chemical analysis, e.g., polarography, and electrometric or conductometric titrations; in chemical synthesis, e.g., dyestuffs, fertilizers, plastics, insecticides; in biology and medicine, e.g., electrophoretic separation of proteins, membrane potentials; in metallurgy, e.g., corrosion prevention, electrorefining; and in electricity, e.g., electrolytic rectifiers, electrolytic capacitors.

ELECTROLUMINESCENCE

Electroluminescence is luminescence excited by electric fields or currents in the absence of bombardment or other means of excitation. Several different types of electroluminescence can be distinguished.

The first observation of what is known as "recombination or injection electroluminescence" was made in 1923 by Lossev, who found that when point electrodes were placed on certain silicon carbide crystals and current passed through them, light was often emitted. Explanation of this emission has been possible only with the development of modern semiconductor theory. If minority charge carriers are injected into a semiconductor, i.e., electrons are injected into *p*-type material or "positive holes" into *n*-type material, they recombine spontaneously with the majority carriers existing in the material. If some of these recombinations result in the emission of radiation, electroluminescence results. Minority-carrier injection may occur not only at point contacts but also at broad area rectifying junctions; in this case the junction must be biased in the forward or "easy-flow" direction, and the electric field in the junction is lower when the voltage is applied than in its absence.

The recombinations in this type of electroluminescence may occur directly between energy

bands of the host material ("recombination radiation" or "edge emission") or by means of impurity or activator centers. In general, the emission intensity is a linear function of the injected current; the emission is "current controlled." This type of emission has now been observed in a wide variety of materials, including SiC, diamond, Si, Ge, CdS, ZnS, ZnSe, ZnO, and many of the so-called III-V compounds such as AlN, GaSb, GaAs, GaP, InP, and InSb. The emission of many of these materials lies in the infrared region of the spectrum. In some cases the efficiency is also very low, values of one emitted quantum per million injected carriers often being observed. However, in some materials the efficiency is high and approaches one emitted photon for each carrier passing across the junction. In GaAs, InAs, InP, and InSb, sufficient radiation intensity may be obtained to cause stimulated rather than normal (spontaneous) emission, resulting in an electrically excited, solid-state LASER.

Another kind of electroluminescence was first observed in 1936 by Destriau. He observed the emission of light from a specially prepared zinc sulfide phosphor suspended in an insulating oil and subjected to an intense alternating electric field by means of capacitor-like electrodes; the emission is "field controlled." Today the phosphor powder is usually embedded in a solid organic (plastic) or inorganic (glass) medium. Thin films of tin oxide or of metal are used to provide transparent, electrically conductive electrodes. Such "cells" can be made with a base of glass, metal, or flexible or rigid plastic material.

This type of electroluminescence, which has been called the "Destriau effect" or "acceleration-collision electroluminescence" has also been observed in ZnSe, Zn₂SiO₄:Mn, BaTiO₃, TiO₂, BN, and some organic materials. The best electroluminescent phosphors, however, are still ZnS and related materials; copper is the most common activator, although ZnS:Cu,Mn is also used. The emission or recombination process in these materials is the same as for excitation by ultraviolet radiation or by cathode rays. The excitation process, however, is quite different. It has been found that to prepare good electroluminescent phosphors, it is necessary to make the material very nonuniform electrically by introducing, on the surface or in defects in the interior of the ZnS particles, segregations of a relatively good conductor, such as ZnO or Cu₂S. The local electric field strength in the neighborhood of these segregations may be a hundred or more times the applied field strength, which is already of the order of 10⁴ to 10⁵ volts/cm. It has been commonly assumed that under the action of these intense local fields, electrons are liberated and accelerated to acquire considerable energy from the field; some of these energetic electrons may collide with and excite or ionize the activator or luminescence centers. However, the mechanism of electroluminescence in ZnS is still not completely understood. Minority carrier injection may also be important in this material.

If a p - n junction is biased in the reverse direction, which results in high internal field strength, other types of emission can occur. For example, the presence of energetic ("hot") carriers can result in emission at energies greater than the forbidden band gap of the material; this has been called "avalanche emission." In this way visible radiation can be generated in germanium or silicon. Emission at energies less than the band gap can also occur. This is attributed to intraband transitions; it is therefore "deceleration radiation" resulting from a change in kinetic energy of the carriers. The efficiency in this case is expected to be quite low.

If metal electrodes such as Al or Ta are immersed in suitable electrolytes and current is passed between them, light emission may also be observed. This "galvanoluminescence" is often electroluminescence in a thin oxide layer formed on the electrode by electrolytic action.

Electroluminescence in ZnS. The intensity of electroluminescence in ZnS increases rapidly as the applied alternating voltage is increased, and also increases slightly less than linearly as the frequency is increased until a region of saturation is approached at frequencies of the order of 100,000 cps. Very high brightness may be achieved (2500 foot-lamberts or more at 20,000 cps). Maximum efficiency is not achieved at the same conditions as maximum brightness. The efficiency of electroluminescence (2.5 to 3.0 per cent) is still low compared to other light sources. Some comparative figures are: electroluminescence, 10 lumens/watt; incandescence, 16 lumens/watt; fluorescent lamp, 70 lumens/watt. Electroluminescence, however, is an area source of light, in contrast to an incandescent lamp, which is essentially a point source, or a fluorescent lamp, which is a line source. Electroluminescent lamps may be made only a fraction of an inch in thickness and of any size or shape. Some electroluminescent phosphors also exhibit a change in emission color as the frequency of the applied voltage is varied.

Another feature of electroluminescent ZnS phosphors of practical importance is the decrease in output during operation. This deterioration is strongly influenced by humidity, temperature, and operating frequency. High temperature and high frequency greatly accelerate the deterioration; the time required to produce a given loss is usually inversely proportional to the frequency. Moisture must be carefully excluded. Lamps have been made with an initial output of 100 foot-lamberts and a life to 50 per cent of this value of 1000 hours (operation at 1000 to 3000 cps). The time required for the output to "build up" after application of a sinusoidal voltage is of the order of a few cycles and hence decreases as the frequency is increased; this time may be decreased by application of a dc bias. The decay time after excitation is independent of frequency.

Phosphors with controlled brightness-voltage characteristics may be prepared for specialized electronic applications. In addition to powder phosphors, continuous films of ZnS a few microns

thick may be prepared. These films operate on alternating as well as direct current and at comparatively low voltage (of the order of 20 volts). Superposition of alternating and direct current can lead to interesting interaction and control of output by small signals.

In electronic applications, electroluminescent phosphors ("electroluminors") may be advantageously used in conjunction with other solid-state components such as nonlinear resistors, photoconductors, magnetic devices, and ferro-electrics for voltage distribution and control. Uses range from single-element control circuits to complicated logic circuits, multielement storage devices, shift registers, light and x-ray image amplifiers and storage panels, and thin large-area image display devices for radar or television. Specially segmented lamps for display of numerical, alphabetical, or other types of information are also available.

Electrophotoluminescence. In addition to electroluminescence proper, other interesting effects occur when electric fields are applied to a phosphor which is concurrently, or has been previously, excited by other means. Such effects are usually termed electrophotoluminescence. One such phenomenon is the "Gudden and Pohl effect," discovered in 1920. Here the phosphor is excited (by ultraviolet radiation, for example) and then an electric field is applied during the afterglow or phosphorescence, or even after the emission has decayed below the limit of detection. A burst of emission is observed with some materials, even those which do not exhibit electroluminescence. In this case, the field acts on electrons in traps that are responsible for the phosphorescence.

Most phosphors, if continuously excited by ultraviolet radiation, x-rays, or cathode rays, show a decrease in emission if an electric field is simultaneously applied. This "field quenching" was first observed by Déchéne in 1935. In 1954, Destriau discovered that some ZnCdS:Mn phosphors excited by x-rays show the opposite effect; i.e., their emission is increased by the application of an electric field. Since that time, a similar enhancement effect has been observed for excitation by light, ultraviolet radiation, cathode-rays, and α -particles. These effects may find application in radiation converters, light amplifiers, and particle detectors.

ELECTROMAGNETIC THEORY

The task of electromagnetic theory is to account for the effects of electrical charges in various states of motion. Although historically electromagnetic theory was developed from Coulomb's celebrated law, it is at present more economic to develop it differently^{9,10}. The macroscopic effects are described with remarkable accuracy by the following set of equations (rationalized mks system of units)

$$\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B} \quad (1)$$

$$\nabla \cdot \mathbf{J} + \frac{\partial \rho}{\partial t} = 0 \quad (2)$$

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} + \mathbf{J} \quad (3)$$

$$\nabla \cdot \mathbf{E} = \frac{\partial \mathbf{B}}{\partial t} \quad (4)$$

$$\mathbf{D} = \epsilon_0 \mathbf{E} \quad (5)$$

$$\mathbf{B} = \mu_0 \mathbf{H} \quad (6)$$

$$\mathbf{J} = \sigma \mathbf{E} \quad (7)$$

provided the functional relationships indicated in Eqs. (5), (6), and (7) are known explicitly. With these equations and the laws of mechanics, classical electromagnetic theory becomes essentially a branch of applied mathematics.

Equation (1), sometimes known as the Lorentz force equation, defines the field quantities, \mathbf{E} , the electric field intensity, and \mathbf{B} , the magnetic induction, in terms of an observable, the force \mathbf{F} on a charge q . In Eq. (1), \mathbf{v} is the velocity of the charge relative to the observer. Equation (2) is a statement of the law of conservation of electric charge in terms of the charge density ρ and the total current density \mathbf{J} . Equation (3) is the differential form of Ampère's law,

$$\oint_{\text{c.c.s.}} \mathbf{H} \cdot d\mathbf{l} = \int_S \mathbf{J} \cdot d\mathbf{S} + I$$

which relates the magnetic field intensity \mathbf{H} to the current, including in addition the displacement current density term $\frac{\partial \mathbf{D}}{\partial t}$, which was added

by Maxwell to make the law applicable to time-varying fields. The term \mathbf{J} represents the total current density. Equation (4) is the differential form of Faraday's law of electromagnetic induction. Equations (5), (6), and (7) are functional relationships, for the most part determined experimentally, by means of which the effects of different materials are accounted for. Mathematically, these equations are employed to reduce Eq. (3) and (4) to a pair of equations in only two unknowns. In free space, Eq. (5), (6) and (7) take their simplest form, respectively, $\mathbf{D} = \epsilon_0 \mathbf{E}$, $\mathbf{B} = \mu_0 \mathbf{H}$, $\mathbf{J} = 0$ (or $\mathbf{J} = \mathbf{J}_s$ a source current independent of \mathbf{E} and \mathbf{H}), where ϵ_0 and μ_0 are constants whose value depends on the system of units (in

the mks system $\epsilon_0 = 8.854 \times 10^{-12}$, $\mu_0 = 4\pi \times 10^{-7}$). Since matter itself is a relatively dilute collection of charged particles, it is always theoretically possible to define terms so that the theory is a description of the effects and interactions of charges in free space, with consequently no essential distinction between \mathbf{D} and \mathbf{E} or between, \mathbf{B} and \mathbf{H} , as indicated above. In practice however effects of materials are usually best handled in another way.^{6,7,9,10} Dielectric polarization effects are accounted for by making the \mathbf{D} vector include the electric dipole moment density \mathbf{P} , $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$, and then introducing a material constant, the permittivity ϵ , such that $\mathbf{D} = \epsilon \mathbf{E}$. The relative permittivity of a dielectric material is then equal to one plus the electric susceptibility. Magnetic polarization effects are handled similarly by defining the field vector \mathbf{B} so that it includes the magnetic dipole moment density \mathbf{M} , $\mathbf{B} = \mu_0 (\mathbf{H} + \mathbf{M})$. The material permeability is then introduced so that it depends upon the magnetic susceptibility analogously, and $\mathbf{B} = \mu \mathbf{H}$. Effects of conductors are represented by a material conductivity σ , such that $\mathbf{J}_c = \sigma \mathbf{E}$. With these simple forms for Eq. (5), (6) and (7), Eq. (3) and (4) take on the useful form

$$\nabla \times \mathbf{H} = \epsilon \frac{\partial \mathbf{E}}{\partial t} + \sigma \mathbf{E} + \mathbf{J}_s \quad (8)$$

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \quad (9)$$

provided μ and ϵ are constant in time. The term \mathbf{J}_s here includes currents arising from charges in free space plus any (source) currents which are independent of \mathbf{E} and \mathbf{H} . If there are no free charges in the region, \mathbf{J}_s includes only the source currents; these latter are known, so Eq. (8) and (9) may be solved for \mathbf{E} and \mathbf{H} . Since the equations are partial differential equations, boundary conditions over closed surfaces are required for unique solutions. Boundary conditions on the field quantities, which must hold at any boundary between two regions, may be derived from these equations. The conditions are: across a boundary (a) tangential \mathbf{E} must be continuous, (b) tangential \mathbf{H} must be continuous, (c) normal \mathbf{D} and normal \mathbf{B} must be continuous. Idealizations of material properties are sometimes helpful. For example, a perfect conductor has no non-static fields inside it, and at its surface, tangential \mathbf{E} and normal \mathbf{B} are zero, tangential \mathbf{H} is equal and perpendicular to any surface current density, and normal \mathbf{D} is equal to any surface charge density.

Two additional equations, especially useful in static problems, may be deduced from Eq. (2), (3) and (4):

$$\nabla \cdot \mathbf{D} = \rho \quad (10)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (11)$$

Solutions to the field equations are most readily obtained by imposing a restriction on the time dependence. If the fields are assumed to be independent of time (static), then Eq. (3) and (4)

or (8) and (9) decouple. One of the equations becomes $\nabla \times \mathbf{E} = 0$. This means that \mathbf{E} is irrotational and may be represented by a scalar potential function ϕ , $\mathbf{E} = -\nabla\phi$. Combining this with Eq. (10) gives the fundamental equation of electrostatics,

$$\nabla^2\phi = -\rho/\epsilon \quad (12)$$

Poisson's equation. This equation for the electrostatic potential is solved by the standard methods of partial differential equations. The boundary conditions on the potential may be found from the boundary conditions on the fields.^{9,10} In practice, it is frequently necessary to solve for the potential and electric field in a restricted region in which the charge density is zero, but the potential at the boundary is held at some particular value(s). The problem then is to solve Laplace's equation, $\nabla^2\phi = 0$, subject to the stated boundary conditions. The standard techniques for solving boundary value problems are employed. However, if the region of interest is partially open, known analytical techniques are sometimes inadequate to solve the problem. In two-dimensional problems of such a difficult type, the method of conformal transformations (conjugate functions) is often helpful.^{8,10}

The main applications of electrostatic theory are in (a) the theory of material properties, (b) the calculation of charged particle trajectories in electron guns, deflection systems, and accelerators (here in conjunction with magnetostatic theory), (c) the calculation of circuit component values, such as capacitance, and (d) the determination of voltage gradients in connection with voltage breakdown problems.

Magnetostatic theory is developed from Eq. (11) and (8). Since \mathbf{B} is divergenceless, it can be represented by the curl of a vector \mathbf{A} , which is known as the magnetic vector potential. Equation (8) can usually be written in terms of this potential as follows:

$$\nabla^2\mathbf{A} = -\mu\mathbf{J} \quad (13)$$

Taken one rectangular component at a time, this equation is of the same form as Poisson's equation [Eq. (12)] and may be solved in the same way. The boundary conditions on \mathbf{A} may be found from those on \mathbf{B} and \mathbf{H} . In regions with no current, Eq. (8) becomes $\nabla \times \mathbf{H} = 0$ so that \mathbf{H} may be represented by a scalar potential function $\mathbf{H} = -\nabla\phi_m$. In such regions then, in view of Eq. (11), the magnetic scalar potential, ϕ_m , must satisfy Laplace's equation

$$\nabla^2\phi_m = 0 \quad (14)$$

provided $\nabla\mu = 0$ in the region. The techniques and solutions of electrostatics are applicable to many magnetostatic problems. Unfortunately, however, in practice many of the systems designed to establish a given magnetic field incorporate ferromagnetic materials. For such materials, the magnetic susceptibility (and hence the permeability) is not independent of the field intensity and the field equations become nonlinear. Present mathematical techniques for

handling nonlinear problems are severely limited. Practical magnetostatic problems are, therefore, frequently solved by some approximation. One of the simplest and most useful approximations is a representation by a magnetic circuit.^{6,8,10} Series and parallel branches of the magnetic circuit may be recognized, and the techniques of linear and nonlinear circuit analysis can be applied to obtain a solution.

Magnetostatic theory is applicable to a myriad of magnetic devices, including deflection systems, motors, generators, relays, magnetic pickup devices, permanent magnets, memories, transducers and coils. To date, the need for particular solutions has frequently arisen before sound analytical methods have been available, so many devices are developed empirically.

Energy is required to establish electric and magnetic fields, and such energy is associated with the fields. The field energy in a given volume may be computed in most cases from a volume integral of one or both of the following energy density expressions $W_e = \frac{1}{2}\epsilon E^2$, $W_m = \frac{1}{2}\mu H^2$, respectively the electrostatic and magnetostatic values.

When the fields are time varying, Eq. (8) and (9) are coupled and must be solved simultaneously. Almost invariably, a potential function such as a vector potential or a Hertz potential is introduced.^{9,10} For example, Eq. (11) implies that \mathbf{B} may be replaced by a vector potential such that $\mathbf{B} = \nabla \times \mathbf{A}$. Equation (9) implies the following equation for \mathbf{E} ,

$$\mathbf{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t} \quad (15)$$

so that \mathbf{H} and \mathbf{E} may be replaced in Eq. (8), and with the condition on \mathbf{A} , $\nabla \cdot \mathbf{A} = \mu\epsilon \partial\phi/\partial t$, the following equations may be obtained for \mathbf{A} and ϕ (σ assumed zero here)

$$\nabla^2\mathbf{A} = \mu\epsilon \frac{\partial^2\mathbf{A}}{\partial t^2} - \mu\mathbf{J} \quad (16)$$

$$\nabla^2\phi = \mu\epsilon \frac{\partial^2\phi}{\partial t^2} - \rho/\epsilon \quad (17)$$

That is, both the vector potential \mathbf{A} and the scalar potential ϕ satisfy a differential equation known as the inhomogeneous wave equation.

Because of their simplicity and practical importance, solutions for those sources and fields which simply oscillate at a single frequency have been studied extensively.^{2,9,10} In this case, the time is eliminated as an independent variable, as if by a transform operation. (In fact, transform methods are often the best means of obtaining transient field solutions.) In the equations, the time derivatives are replaced by frequency multipliers so that the resulting equations are functions of the space variables only. The vector potential may then be found by standard techniques of partial differential equations and boundary value problems. Having \mathbf{A} , the field quantity \mathbf{B} is found from $\mathbf{B} = \nabla \times \mathbf{A}$ and \mathbf{E} is found from

Eq. (8). In practice, a theorem which can be derived from the field equations, called the reciprocity theorem,^{2,3,10} is often helpful. The theorem relates the fields E_a and E_b produced respectively by a pair of current distributions J_a and J_b . The theorem is

$$\iiint E_a \cdot J_b dv = \iiint E_b \cdot J_a dv \quad (18)$$

For example, if J_b is selected to be a point current at point P , directed along x (represented mathematically by a Dirac delta function), then Equation (18), $E_{ax}(P) = \iiint E_b \cdot J_a dv$, gives a formula for the computation of the field due to J_a which is equivalent to a superposition integral involving a Greens function.

Perhaps the most fundamental problem of electromagnetic theory is the determination of the fields of a point charge, at rest, in oscillation, or in some general state of motion. For a point charge q , at rest in free space, the solution may be obtained by solving Eq. (12) in spherical coordinates. With the point charge at the origin, symmetry conditions may be employed to eliminate the angular variation, and the remaining differential equation in r can be solved subject

to Eq. (10) to give $\phi(r) = \frac{q}{4\pi\epsilon_0 r}$ for the potential associated with the point charge. A superposition integral

$$\phi = \iiint \frac{\rho dv}{4\pi\epsilon_0 r} \quad (19)$$

may then be employed to find the potentials associated with more complicated distributions. The field of an oscillating dipole, which is equivalent to a point alternating current, is also of great interest. This solution may be obtained from Eq. (16) (single frequency version). If the point current is directed along z , the z -component of the vector potential may be found by a procedure similar to that employed for a point charge. The final result is

$$A_{z0} = \frac{I\Delta z}{4\pi\mu_0 r} \cos \omega(t - \sqrt{\mu_0\epsilon_0}r) \quad (20)$$

where $I\Delta z$, the current moment, is equal to $q\Delta z$, the maximum dipole moment of the oscillating dipole. The factor $(t - \sqrt{\mu_0\epsilon_0}r)$ exhibits the time delay required for the effects of the oscillating charges to propagate to distant points. The electric and magnetic fields may be computed from Eq. (20) as indicated above. The magnetic field strength produced by an oscillating dipole (point current) is, for example, in the spherical coordinate system (r, θ, φ)

$$H_\varphi = \frac{I\Delta z}{4\pi} \sin \theta \left[\frac{\cos \omega(t - \sqrt{\mu_0\epsilon_0}r)}{r^2} - \frac{\omega \sqrt{\mu_0\epsilon_0}}{r} \sin \omega(t - \sqrt{\mu_0\epsilon_0}r) \right]$$

This form like Eq. (20), shows that the crests and valleys of the field oscillations are propagated in spherical waves at the speed of light $v = (\mu_0\epsilon_0)^{-1/2}$. The solution for a point current may be employed in an integral similar to Eq. (19) to find the vector potential of a more complicated distribution of current. Such solutions may also be employed to find the radiation patterns and input impedances of antennas.

The potentials and fields produced by a charge moving in an arbitrary way may also be obtained.^{3,9} The results may be found in Stratton, 9, pp. 475-476.

In regions free of source currents and charges, the fields and potential satisfy the homogeneous wave equation [for example Eq. (16) with $J = 0$]. Then one of the simpler solutions which can be obtained is that of the plane electromagnetic wave. With appropriate orientation of the rectangular coordinate system, the solutions show that plane waves may progress along z , with components as follows:

$$E_r = E_0 \cos \omega(t - \sqrt{\mu_0\epsilon_0}z)$$

$$H_\varphi = E_0 \sqrt{\frac{\epsilon_0}{\mu_0}} \cos \omega(t - \sqrt{\mu_0\epsilon_0}z)$$

where E_0 is an arbitrary constant amplitude. Note that E , H and the direction of propagation are all perpendicular to one another. The Poynting vector, $S = E \times H$, points in the direction of propagation. Moreover, the power carried through a closed surface by an electromagnetic field may be computed from a surface integral of the Poynting vector.

With single frequency fields in source free regions, both H and E can be represented by vector potentials,^{2,9,10} $H_1 = \nabla \times A_1$, $E_2 = \nabla \times A_2$, and moreover the coordinate systems may be oriented so that A_1 and A_2 each have a single component¹⁰. In cylindrical systems, this single component is commonly along z . H_1 is then transverse to z (TM) and the set of fields, E_1 , H_1 , derivable from A_1 , are called TM fields. E_2 is likewise transverse to z and the set of fields, E_2 , H_2 , derivable from A_2 , are called TE fields. This procedure is particularly helpful in problems involving transmission lines and waveguides and is developed in detail in Weeks¹⁰, ch. 4-6.

Some of the most interesting and fundamental problems of electromagnetic theory are concerned with the scattering and diffraction of electromagnetic waves.^{2,3,8-10} For example, exact solutions are available for the scattering by cylinders and spheres, as well as an infinitely long slit. Approximate solutions are available for many other shapes. The methods are those outlined above, supplemented by generalizations of the principles of Huygens and Babinet.

Another topic of wide interest is the nature of fields in ionized gases or plasmas. The applications range from ionospheric propagation to microwave devices to nuclear apparatus to magneto-hydrodynamics to satellite reentry problems.

The simplest theory for these effects is developed from Eq. (3) and (4) (single frequency version) by separating the ion current term $J_e - \rho v$ from J , and employing Newton's law to eliminate v in favor of E , H and whatever mechanical constraints are applicable^{4,9,10} (see PLASMAS).

Effects peculiar to charges moving with very high velocities have not been included in this discussion (see RELATIVITY THEORY). Quantum effects are also discussed elsewhere (see QUANTUM ELECTRODYNAMICS and QUANTUM THEORY).

ELECTRON

The electron is the smallest known electrically charged particle. Its existence and characteristics were inferred from many experiments clustered in and around the last decade of the nineteenth century. In the 1830's, Faraday had tentatively suggested that his experiments in ELECTRO-CHEMISTRY could be interpreted in terms of a small unit of charge attached to ions. This notion of individual "atoms of charge" was somewhat eclipsed, however, by the enormous success of Maxwell's theory of electromagnetism, which was generally interpreted, by 1880, as favoring a view that electrical phenomena were due to continuous charge distributions and motions. G. Johnstone Stoney, in 1874, and Helmholtz, in 1881, had suggested again an atomic interpretation of electricity, but it was not until the brilliant

experiments of Perrin, J. J. Thomson, Zeeman, and others in the 1890's that the concept of the electron received firm experimental foundation. Later experiments and theory (Millikan, Bohr, etc.) established the constancy of the electronic charge and interwove the concept of an electron of definite charge and mass into the basic structure of the atom.

The Cathode Ray Controversy. After the discovery of the cathode ray in high-vacuum discharge tubes by Plücker in 1858, there developed, with the experiments of Goldstein, Crookes, Hertz, Lenard, and Schuster, a controversy over the nature of the rays. A predominately German school held that the rays were a peculiar form of electromagnetic rays. The British physicists thought they were negatively charged particles. The controversy provides a classic "case history" of the typical scientific controversy in which two quite different models both explain most, but not all, of the observable facts. The proponents of each model designed ingenious experiments and in some cases were so trapped in their preconceptions that they badly misinterpreted their observations. The Germans were especially impressed by the fact that the rays could go through thin foils—something no known particles could do. The British were firm in pointing out that the rays could be deflected by magnetic fields—something not possible with electromagnetic waves. Hertz, in what he thought was a crucial experiment, was unable to detect deflection of the rays by electric fields, but this very phenomenon was demonstrated by J. J. Thomson and made the basis for his conclusive experiments that the rays had velocities less than that of light. Thomson showed, further, that if one assumed that the rays were composed of particles, then the particles had the same ratio of charge to mass regardless of the cathode material or the nature of the residual gas. Perrin's classic experiment, meanwhile, proved that the rays did indeed convey negative charge. In the decade between 1896 and 1906, Thomson and others showed that negatively charged particles from sources other than cathode rays had the same ratio of charge to mass: the negative particles emitted by hot filaments in the Edison effect, the beta rays emitted by some radioactive materials, and the negative particles emitted in the photoelectric effect that had so ironically been discovered by Heinrich Hertz in his great experiment which demonstrated the electromagnetic rays predicted by Maxwell's equations.

Thomson's Determination of e/m . In 1897 Thomson devised an apparatus in which he could deflect a beam of cathode rays with a magnetic field of induction B and also with an electric field of strength E . If the fields are perpendicular to each other, and to the original path of the beam, and if they occupy the same region, then (with proper polarities and magnitudes of fields) the electric force on the beam can equal the magnetic force, so that the beam hits the same point on a fluorescent screen as when no fields are applied. If e is the charge of a

given particle, m its mass, and v its velocity, $v = E/B$. Thus, velocities of typical cathode ray beams could be measured. If the magnetic field is used alone, and the curvature R of the beam is measured, then one can equate centripetal and magnetic field forces $mv^2/R = Bev$, and then deduce $e/m = v/BR$. With v known from the previous experiment, e/m can be calculated. Thomson's early values were not very precise, but later experiments of a similar type gave values close to 1.76×10^{11} coulombs/kg. More recent experiments, drawing on measurements of many kinds, give $e/m = (1.75890 \pm 0.00002) \times 10^{11}$ coulombs/kg.

The Zeeman Effect. In 1896 Zeeman discovered the broadening of spectral lines when a light source was in a strong magnetic field. Experimental refinements by Zeeman and others, and theoretical work by Lorentz and Zeeman, permitted the interpretation of this effect as due to the influence of the magnetic field on oscillating or orbiting negatively charged particles within the light-emitting or absorbing atoms. From the spectroscopic data, the ratio of charge to mass of these hypothetical particles could be shown to be equal to that of cathode rays. The Zeeman effect thus provided the first experimental evidence that the negative particles emitted by atoms when heated (Edison effect) or subject to high fields and/or ionic bombardment (cathode rays) or bombarded by short-wavelength light (photoelectric effect) were, indeed, actual constituents of the atoms and were probably responsible for the emission and absorption of light.

The Charge on the Electron. In the decade following 1897, many different methods were evolved for determination of ionic charges. Some methods depended upon measuring the total charge of a number of ions used as nuclei for cloud droplet formation. Other methods were more indirect—experiments, for example, which, combined with the kinetic theory of gases, could give crude values for avogadro's number, N (see MOLE CONCEPT). By dividing the Faraday constant (the charge carried in electrolysis by ions formed from one gram-atom of a univalent element) by N , one could determine the average charge per ion. Similarly, the constants in Planck's theory of blackbody radiation, when evaluated experimentally, could provide a numerical value for N , as could certain experiments in radioactivity. All such methods gave values of N of the order of 6×10^{23} , and hence 1.6×10^{-19} coulomb for the ionic charge. None of these methods measured individual charges; strictly speaking, the value for the ionic charge could be thought of only as an average value.

Millikan's experiments with single oil drops, beginning in 1906, provided a method for measuring extremely small charges with precision. He was able to show that the charge on his drops was *always* ne , with $e = 1.60 \times 10^{-19}$ coulomb (modern value) and n a positive or negative integer.

He observed the motions of very small charged oil drops in uniform vertical electric fields. The

drops were so small that they moved with constant velocity (except for Brownian fluctuations) for a given force. The force in each case was due to gravity acting on the mass of the drop and to the electric field (if any) acting on the charge, q , on the drop. The charge on a given drop could be changed by shining x-rays upon it. Using Stokes' Law, in a form modified to correct for the fact that the drops were *not* large in comparison to the inhomogeneities of the surrounding air, and the velocity of a drop in free (gravitational) fall, Millikan could infer the diameter and mass of a given drop, and then calculate its charge. The charge q always equaled ne . (See reference 1 or 2 for experimental details.) A few other physicists, in similar experiments, thought they had detected electric charges smaller than Millikan's e , but their experimental techniques were probably faulty.

Millikan's experiment did not prove, of course, that the charge on the cathode ray, beta ray, photoelectric, or Zeeman particle was e . But if we call all such particles electrons, and assume that they have $e/m = 1.76 \times 10^{11}$ coulombs/kg, and $e = 1.60 \times 10^{-19}$ coulomb (and hence $m = 9.1 \times 10^{-31}$ kg), we find that they fit very well into Bohr's theory of the hydrogen atom and successive, more comprehensive atomic theories, into Richardson's equations for thermionic emission, into Fermi's theory of beta decay, and so on. In other words, a whole web of modern theory and experiment defines the electron. (The best current value of $e = (1.60206 \pm 0.00003) \times 10^{-19}$ coulomb.)

The Wave Nature of the Electron. In 1924, L. DeBroglie suggested that the behavior of electrons within atoms could be better understood if it were assumed that the motion of an electron depends upon some sort of accompanying wave, the length of which would be h/p (h = Planck's constant and p the momentum of the electron). This suggestion led to the development of QUANTUM MECHANICS by Schrödinger, Heisenberg, and others. The concept of electron waves provided an explanation for experiments on reflection of electron beams by metallic crystals, carried out from 1921 onward by Davisson and others, and provided an impetus for the experiments of G. P. Thomson on the diffraction of electron beams by thin films (see ELECTRON DIFFRACTION).

Other Characteristics of Electrons. In applying quantum mechanics to certain problems in atomic spectroscopy, in 1925 and 1926, Pauli, and Goudsmit and Uhlenbeck found that electrons must possess angular momentum of amount $\pm \frac{1}{2}(h/2\pi)$. Dirac's work on a generalized quantum theory of the electron showed that it possessed a related magnetic dipole moment of magnitude $eh/4\pi mc$ (see ELECTRON SPIN). The ratio of the dipole moment to the angular momentum (e/mc) is larger than can be accounted for in classical terms with any homogeneous wholly negative model. The concept of electronic dipole magnetic moment is essential not only in spectroscopy but in theories of ferromagnetism (see MAGNETISM).

One may speak of the "classical radius of the electron," $a = e^2/mc^2$, derived by setting the self-energy of the coulomb field of a charge e contained at a radius a equal to the relativistic rest energy, mc^2 of the electron. This $a = 2.82 \times 10^{-13}$ cm, comfortably smaller than any atom, but larger than the usual estimates of sizes of protons and neutrons.

Positive Electrons. Dirac's paper in 1928 could be interpreted as predicting the existence of electrons that are positive. But until such particles were found experimentally by C. D. Anderson in 1932 in cloud chamber pictures of cosmic ray particle tracks, most physicists preferred other interpretations of Dirac's paper. Positive electrons, or **POSITRONS** are now known (1) to occur as decay products from certain radioactive isotopes, (2) to be produced (paired with a negative electron) in certain interactions of high-energy gamma rays with intense electric fields near nuclei, and (3) to be the product of certain decays of certain mesons. In principle, positrons could form anti-atoms with nuclei made from anti-protons and anti-neutrons, but in practice almost all positrons produced in the observable universe quickly meet their end by annihilating themselves together with some hapless negative electron. The end product of a positron-electron annihilation is a pair of gamma rays.

Applications of Electrons. Aside from their inherent usefulness in physical theories of magnetic, electrical, optical, and mechanical properties of matter, electrons either in beams or in conductors can be made to do all sorts of useful things. Cathode ray oscilloscopes, electron microscopes, image converters, certain memory devices for computers, television picture tubes, and most "radio tubes" depend upon beams of electrons controlled by electric or magnetic fields (see **ELECTRON OPTICS**). In ordinary metallic conductors, electricity is carried primarily by electrons. The behavior of electrons in **SEMI-CONDUCTORS** and in **superconductors** (see **SUPER-CONDUCTIVITY**) has in recent years been the basis both of intense theoretical interest and of interesting and useful devices.

ELECTRON DIFFRACTION

The discovery of electron diffraction independently by C. J. Davisson and L. H. Germer (1927) and G. P. Thomson (1927) verified L. de Broglie's earlier hypothesis (1924) that matter exhibits both corpuscular and wavelike characteristics. This hypothesis served as a stimulus for the formal development of quantum mechanics by E. Schrödinger, M. Born, W. Heisenberg, and others. Following this momentous discovery, which eventually resulted in the award of a Nobel Prize to Davisson and Thomson, electron diffraction was immediately utilized as a tool for the study of the structure of matter.

Electron, x-ray and neutron diffraction are all used for structure studies. Electron diffraction is used particularly for those structural studies that involve small numbers of atoms. This is due to the strong interaction of electrons with matter. Thus the principal area of application of electron diffraction is for the study of thin films, surfaces, gases and small samples.

The different energy ranges that were used in the Davisson-Germer and Thomson experiments provide a natural division for a description of the types of equipment, areas of application, and analytical techniques that have evolved since 1927. These experiments were performed with electrons having energies in the vicinity of 150 eV and 15 keV, respectively. De Broglie's relationship $\lambda = h/mv$, where h is Planck's constant and λ is the wavelength associated with a mass m traveling with a group velocity v , reduces to $\lambda \approx \sqrt{150/V}$ for electrons in the nonrelativistic limit, where V is the accelerating voltage and λ is expressed in Angstroms. The two experiments thus used electrons having a wavelength of approximately 1 and 0.1 Å. The longer wave-length is comparable to the spacing between atoms in crystals.

While 50-keV electrons, which are used in most commercial electron diffraction instruments, penetrate to a depth of about 10^3 Å into a crystal, 150-eV electrons penetrate only about 10 Å. Since the higher-energy electrons are capable of passing through the several layers of adsorbed foreign material that normally are present on the surface of a crystal, surface cleanliness and therefore the vacuum requirements for 50-keV electron diffraction are not as stringent as those for low-energy electron diffraction. This factor, in addition to the relative ease in focusing intense high-voltage beams, and individual interests, resulted in the wide application of high-energy electron diffraction for structure studies. A typical instrument of this type operates at about 50 keV, has provisions for producing and focusing the electrons, contains specimen manipulators, photographic means to record the diffraction patterns and is contained in a chamber capable of being evacuated to 10^{-5} torr. Diffraction patterns are obtained either by transmission of the beam through very thin films or by working at grazing incidence and reflection. The grazing incidence technique is potentially capable of resolving structures having a monolayer thickness.

One of the most common uses of 50-keV electron diffraction by transmission or reflection is for the study of films on amorphous, polycrystalline and single crystal substrates. This includes films that have been formed by the oxidation or corrosion of a surface, as well as those formed by the deposition of material on a substrate. In many instances these films consist of crystallites having an orientation that is related to the structure and orientation of the substrate material.

In the past few years, the transmission ELECTRON MICROSCOPE has become widely used for the study of atomic arrangements at lattice imperfections, such as dislocations and stacking faults. Image contrast is obtained by local differences in the intensities of diffracted beams. In addition, many electron microscopes are constructed in such a way that it is possible to obtain the diffraction pattern associated with the material in the area being studied.

Electron diffraction in this energy range is especially useful for the determination of the atomic arrangements, bond distances, bond angles, and mean square atomic vibrational amplitudes in gaseous molecules.

Low-energy electron diffraction was used by only a few groups until approximately 1960. Improved diffraction equipment, which enabled the direct display of the diffraction pattern on a fluorescent screen by accelerating the diffracted electrons after they had passed through grids, and the commercial availability of ultrahigh (10^{-10} torr) vacuum equipment, resulted in a resurgence of interest in this field. The structure of clean surfaces, the arrangements of foreign atoms on these surfaces at a monolayer or less coverage, and many aspects of the initial stages in the oriented overgrowth of thin films have been studied with electrons having energies in the range of 2 to 10^3 eV. It has been revealed that the atomic arrangement at the clean surfaces of semiconductors such as germanium and silicon is quite unlike that found in the bulk of these materials. At low coverages, foreign atoms are normally adsorbed in structures that have a symmetry and dimensions that are simply related to the orientation of the substrate plane. A multitude of such structures has been found on semiconductors and metals. Their atomic array is dependent on many parameters, such as the amount of adsorbed material, the temperature, orientation and cleanliness of the substrate.

Fundamental properties of solids, such as characteristic energy losses, atomic mean square vibrational amplitudes and electron range, have also been investigated by both high- and low-energy electron diffraction.

ELECTRON MICROSCOPE

The electron microscope is a device that forms magnified images by means of electrons. The electrons are usually accelerated to between 50 and 100 kV. The microscope magnifies in two or three stages by means of electromagnetic or electrostatic lenses.

In 1878 Ernst Abbé proved that the resolution of the optical microscope is limited by the wavelength of light. No matter how perfect and free of aberrations the optical system is, the image of a geometrical point is not a point but a disc, the "Airy disc." Regardless of any further magnification, two separate points cannot be resolved as separate unless their centers are the distance d apart, whereby d is the diameter of the Airy disc referred to the object plane:

$$d = \frac{0.5 \lambda}{n \sin \alpha} \quad (1)$$

where

- λ = wavelength of the illuminating light
- n = index of refraction of medium between object and lens (in air, $n = 1$)
- α = aperture of lens, i.e., half-angle of collected light beam
- $n \sin \alpha$ = NA = numerical aperture of lens (in air, $NA_{\max} = 0.95$).

Even if we go to the extreme of using the ultraviolet line of mercury ($\lambda = 253.7$ nm*), oil immersion optics ($NA = 1.4$), quartz lenses and microphotography, the best resolution obtainable is still:

$$d = 110 \text{ nm}$$

The electron microscope makes use of the wave properties of the moving electron. Its "de Broglie" wavelength is:

$$\lambda = \frac{h}{mv} = \frac{1.23}{V^{1/2}} \text{ [nm] for nonrelativistic electrons (below 20 kV)} \quad (2a)$$

and

$$\lambda = \frac{1.23}{(V + 10^{-6} V^2)^{1/2}} \text{ [nm] for relativistic electrons} \quad (2b)$$

where

- h = Planck's constant
- m = mass of electron
- v = velocity of electron
- V = accelerating voltage in volts.

For electrons of $V = 50$ kV the wavelength is therefore:

$$\lambda_{50 \text{ kV}} = 0.00535 \text{ nm}$$

* 1 nanometer (nm) = 1 millimicron (m μ) = 10 angstrom units (Å).

Objective lenses for electrons, unlike those for light optics cannot be made free of spherical aberrations. They have to operate with numerical apertures that are 500 to 1000 times lower. The best theoretical resolution for magnetic lenses working with electrons of 50 kV energy is:¹

$$\delta = 0.21 \text{ nm}$$

The best practical resolution is between 0.5 and 1 nm.

The first electron microscope was built by M. Knoll and E. Ruska at the Technical University of Berlin early in 1931. It had two electromagnetic lenses in series and achieved a modest magnification of 17. Knoll and Ruska improved the electron microscope step by step. They added a condenser lens and built an iron shield with a narrow center gap around their magnetic lens.

Ruska, working from 1932 by himself, equipped the magnetic lenses with narrow pole pieces and was able to demonstrate in 1933 a resolution of 50 nm (magnification of 12,000), better than the best obtainable optical resolution. Figure 1 shows a functional diagram of his supermicroscope. Figure 2 shows the details of one of his lenses.

Parallel to the development of the magnetic electron microscope went the development of an electrostatic one. In 1931, Brüche and Johansson of the Research Institute of A.E.G. of Berlin imaged the emitting surface of the cathode with an electrostatic immersion objective. In 1932, they employed unipotential or Finzel-lenses used now, almost exclusively, in general-purpose electrostatic microscopes.

Magnetic Lenses. A charged particle entering a uniform magnetic field perpendicular to the

FIG. 1. First Supermicroscope (Ruska 1933).

FIG. 2. Magnetic Lens (Ruska 1933).

lines of force will describe a circle; moving parallel to them, it will not be deflected. The radius of the circle that the particle describes, the "cyclotron radius", is:

$$\rho = \frac{m v}{e B} \quad (3)$$

where

m = mass of particle
 e = charge of particle
 v = velocity
 B = magnetic field intensity (gauss).

The circle described by an electron is

$$\rho_e = 3.372 \frac{\sqrt{V}}{B} \text{ [cm] for nonrelativistic electrons} \quad (4a)$$

$$\rho_e = \frac{1}{B} \sqrt{11.3V + 1.11 \times 10^{-5} V^2} \text{ [cm] for relativistic electrons} \quad (4b)$$

where V is in volts and B is in gauss.

The time it takes a particle to describe a cyclotron circle is:

$$\tau = \frac{2\pi\rho}{v} = 2\pi \frac{m}{e B} \text{ [sec]} \quad (5)$$

A charged particle entering a uniform magnetic field at an angle will describe a cycloid. While its velocity component normal to the field lines causes it to describe a circle, the velocity component parallel to the field lines remains unchanged. Since the time required to describe a circle is independent of the normal velocity, all circles, large or small, are traversed in the same time interval. In an electron beam with low divergence where, therefore, the velocities parallel to the magnetic field (v_z) are identical, all electrons leaving one point P on the axis will meet downstream at another point P' at a distance

$$d = \frac{v_z}{\tau} \quad (6)$$

with angles to the axis identical to those they had at point P (see Fig. 3).

A "long" magnetic lens, having a uniform magnetic field extending from the object to the image point, will form an upright picture of the object with an image to object ratio of 1 to 1.

A "thin" magnetic lens is a lens with a magnetic field short compared to the object-to-image distance. A "weak" thin lens is a lens with the focal length large compared to the axial length of the magnetic field. The refractive power, i.e., the reciprocal of the focal length, of such a lens is determined by:

$$\frac{1}{f} = \frac{0.022}{V} \int_{-\infty}^{+\infty} B_z^2 dz \text{ [cm}^{-1}] \quad (7)$$

It images according to the general optical equation:

$$\frac{1}{f} = \frac{1}{a} + \frac{1}{b} \quad (8)$$

FIG. 3. Cycloids, described by electrons in uniform magnetic field.

where a is the object distance and b is the image distance. The picture is turned around from the position of the object. The angle it is turned is determined by:

$$\theta_i = \frac{0.149}{\sqrt{V}} \int_{-\infty}^{+\infty} B_z dz \text{ [radians]} \quad (9)$$

The objective and projector lenses of the electron microscope require extremely short focal lengths in order to obtain high magnifications without going to extremely long microscopes. These lenses have, therefore, pole pieces which limit the extent of the magnetic field, both in the axial and radial dimensions. The treatment of strong, thin magnetic lenses can be found in references 2 and 3.

Electrostatic Lenses. *Immersion lenses* consist of two apertures or two coaxial cylinders at different potentials. They are important as lenses for television or oscillograph cathode-ray tubes. The electrostatic lenses used exclusively as objective or as projector lenses in electron microscopes are *unipotential* or *Einzel-lenses*. They have the same potential on either side of the lens. They consist of three apertures: the two outer apertures are at ground or anode potential, and the center electrode can have either a positive or negative potential. Regardless of whether a positive or a negative potential is applied, the lens will always be convergent. Figure 4(a) shows the equipotential lines of such a lens; Fig. 4(b) shows the focal length vs V_L/V_0 for this lens, where V_L is the voltage applied to center electrode and V_0 the cathode potential. Figure 5 shows the design of a typical electrostatic lens.

Main Features of Transmission Microscope. The normal electron microscope is a transmission

FIG. 4. Unipotential or Einzel-lens:
(a) Equipotential Lines (From H. Mahl and A. Pendzich, *Zeitscher. Techn. Phys.*, **24**, 38-42 (1943))

microscope where the image is formed by electrons which have passed through the specimen. It is composed of the following major sections: electron gun, condenser lens, specimen chamber, objective lens, projector lens, viewing and photographing chamber. It has the following ancillary equipment: (1) power supplies for high voltage, heater voltage, and focusing currents; (2) vacuum systems.

The *electron gun* generates the electron beam which illuminates the object. It has to provide the required electron density within a certain limited divergence. It consists of a hairpin tungsten filament enclosed in a cup-shaped electrode at cathode or a more negative potential. While the anode facing the cathode is at ground potential, the cathode is maintained at a high negative potential, usually between 50 and 100 kV.

The *condenser lens* or lenses increase the electron density reaching the specimen by concentrating the beam. An aperture in the condenser lens of 0.25 to 0.5 mm diameter reduces the amount of stray electrons reaching the specimen.

The *objective lens* provides the first magnification. It is a strong, thin lens with a high refractive power. It has, therefore, narrow precision pole pieces. The object is brought very close to the magnetic gap.

The different shades of density of the object are reproduced by the scattering of electrons. The electrons removed from the image cone of each point will reach the image plane at random. They will, therefore, produce fogging of the image. In order to remove as many stray electrons as possible, an aperture of 25 to 100 μ is inserted in the objective gap.

The *projector* or *image lens* selects a small portion of the intermediate image produced by the objective lens and magnifies it again. A third electron-optical magnification is in some cases produced by a second projector lens.

The *specimen chamber* is located above the objective lens. It can be opened for inserting the specimen, usually without disturbing the vacuum in the main column. It has adjustments that permit shifting the specimen in the object plane in order to locate the area of interest. Some models have special facilities to keep the specimen at certain high or low temperatures.

The *viewing chamber* at the bottom of the microscope column contains the fine-grain fluorescent screen that can be observed through glass windows either directly or through a monocular or binocular telescope. If a permanent record is desired, the fluorescent screen is moved aside and a photographic plate inside a plate holder is exposed. The electrons produce a latent image

FIG. 5. Typical Electrostatic Lens. Based on article by H. Mahl, *Jahrb. AEG Forschung.*, **7**, 43-56 (1940).

directly. Each plate can be removed from the vacuum separately.

In some cases when an extremely high magnification, for instance 100,000 times, is desired, it may pay to magnify electron-optically to a somewhat lower magnification and to add a final photographic enlargement later; the adjustment of the electron microscope is then much easier, since the field of vision is so much larger.

A photographic film is used sometimes, instead of plates, if a series of pictures is to be taken and if extremely high resolution is not required.

The *vacuum system*, generally maintaining a vacuum of 10^{-4} to 10^{-5} torr (1 torr = 1 mm Hg), consists usually of an oil diffusion pump backed by a mechanical forepump. A second mechanical pump is sometimes used to purge the specimen chamber and the photographic plate lock before they are opened to the main vacuum column. A water or liquid-nitrogen-cooled baffle is used to prevent backstreaming of oil vapor into the chamber.

Power Supplies. The voltage regulation required for the power supplies of the electrostatic microscope is not very critical. As long as the lens voltage and cathode potential maintain the same linear ratio—very often they are identical—a good image is obtained.

The refractive power of the magnetic lens depends directly on the square of the magnetic flux, which is proportional to the lens current if the magnetic circuit is not saturated, and varies inversely with the cathode potential [see Eq. (7)].

It is, therefore, paramount that all power supplies be extremely well-regulated. Assuming a maximum permissible unsharpness of 1 nm, Zworykin *et al.*¹ give the following values for maximum permissible instabilities:

$$\text{High voltage power supply: } \frac{\Delta V}{V} = 1.1 \times 10^{-4}$$

$$\text{Objective lens: } \frac{\Delta I_1}{I_1} = 0.55 \times 10^{-4}$$

$$\text{Projector lens: } \frac{\Delta I_2}{I_2} = 1.3 \times 10^{-4}$$

$$\text{Condenser lens: } \frac{\Delta I_3}{I_3} = 1 \times 10^{-4}$$

The values guaranteed by various manufacturers are often considerably lower, especially during the short exposure time.

Other Types of Electron Microscopes. Several types of electron microscopes that are different from the transmission microscope have been described, but none of them has attained its popularity.

The *emission electron microscope* has been used to study various surface phenomena. The *thermionic emission microscope* is almost as old as the transmission microscope. The first electrostatic microscope and one of the first electromagnetic microscopes were used to study electron

emission from hot cathodes. Secondary emission and photoemission have also been studied. For the *field emission microscope*, see FIELD EMISSION.

The *shadow microscope* of Boersch^{5,6} is an inverted microscope. Two electrostatic lenses with large object and small image distances reduce the size of the crossover point (the smallest beam diameter located between grid and anode) by several orders of magnitude. This fine spot is the illuminating source for the object, which is brought close to the image plane of the second lens. The magnification depends on the ratio of the spot to object and the spot to screen distances. No lenses are required between the object and the screen. The ultimate resolution depends only on the size of the spot. The resolution could be of the same order as that of the transmission microscope. The spot-to-object distance is very critical, but it is difficult to reproduce. It is, therefore, difficult to measure the magnification.

The *scanning microscope*, first proposed by M. von Ardenne in 1938, also uses an inverted microscope. In this case, the fine spot is deflected in a raster, similar to the television scan, across the object. The deflection of the beam takes place between the first and the second reducing lens. In this manner, it is not necessary to introduce a deflection system between the last lens and the object which would increase the image distance considerably. A recording drum is mounted below the specimen, which makes one revolution per scanning line. The paper speed is 2500 times the speed of the spot across the specimen. This ratio is, therefore, the image magnification. To increase the signal-to-noise ratio, a slow scan is used. It takes a period of 10 minutes or more to record one picture.

Another scanning microscope was built by Zworykin and co-workers.⁷ It uses a collector above the specimen to collect secondary electrons emitted from the surface of an opaque object. The collected electron current is amplified and modulates the electron beam current of a display tube whose x and y deflection are synchronized with the microscope beam scan.

Mirror Microscope.⁸ If we were to apply to the unipotential lens in Fig. 4(a) a potential much more negative than that of the cathode, a zero potential line would cross the center of the lens, which the electrons cannot penetrate. They would have to turn back. The unipotential lens is then turned into a mirror. If the electrons are able to penetrate into the convergent center section of the lens, the mirror will act as a convergent mirror [electron path 1 in Fig. 4(a)]. If the potential of the center electrode is so highly negative that the electrons can penetrate only into the divergent outer section, the mirror is divergent (electron path 2).

If the center electrode of the unipotential lens is closed and is kept at cathode or a somewhat more negative than cathode potential, the unipotential lens would be transformed into a divergent immersion mirror. By keeping the potential of this electrode very close to cathode potential, the electrons will penetrate close to

its surface before they turn around. At the lowest point, they will have only a very small tangential energy. They are, therefore, easily influenced by various parameters of the metal surface. e.g., by weak magnetic fields, by electrostatic charges or by distortions in the electrostatic field close to the surface due to surface roughness. They form, therefore, an enlarged image of certain surface features if a fluorescent screen is mounted some distance away from the mirror, e.g., on the underside of the preceding lens. This screen will always have a small aperture in order to admit the electron beam to the mirror.

ELECTRON OPTICS

The invention of wave mechanics in 1926 by Heisenberg and Schrödinger saw a revolution in physics. It became apparent that the ideas of classical dynamics could be formally replaced when a stream of particles was considered. According to the well-known De Broglie hypothesis, a wavelength λ can be assigned to any material particle such that

$$\lambda = h/mv \quad (1)$$

where h is Planck's constant, m is the particle mass, and v is the particle velocity.

As one of the many consequences of these ideas, the new science of electron optics emerged.

In the same year, Busch demonstrated that the action of a short axially symmetrical magnetic field on a beam of electrons was similar to that of a glass lens on light. Terms used before then in optics found their use in describing electron devices. Electron "lenses" and "mirrors" having "focal lengths" and "resolutions and aberrations" were described. This analogy has proved useful in the study of the behavior of electrons in electronic valves, magnetrons and klystrons, traveling wave tubes, cathode ray tubes and electron microscopes, to name only a few devices. The original concept of the electron microscope was evolved by direct analogy with the light microscope.

An electron which has fallen through a potential V has a kinetic energy $\frac{1}{2}mv^2 = eV$. Hence $v = \left(\frac{2eV}{m}\right)^{1/2}$ and using Eq. (1), we obtain the useful formula expressing electron wavelength in terms of volts

$$\lambda = \left(\frac{150}{V}\right)^{1/2} \quad (2)$$

where λ is in angstroms.

In light optics, the least resolvable distance S between two objects is given by the Abbé expression $S = \frac{\lambda}{2n \sin i}$, where n is the refractive index of the material between object and lens and $2i$ is the angle subtended at the lens by the object; $n \sin i$ is called the numerical aperture. In the case of white light of equivalent wavelength $\lambda = 5600 \text{ Å}$,

$$S_{\text{(minimum, light)}} = 1800 \text{ Å, i.e., } 1.8 \times 10^{-5} \text{ cm}$$

Using the same expression and Eq. (2), which gives λ for an electron 0.04 Å for $V = 100 \text{ kV}$,

$$S_{\text{(minimum, electrons)}} \approx 0.04 \text{ Å}$$

i.e., small fractions of an angstrom can be resolved. However the theory does not take into account the fact that lenses are imperfect. Spherical aberration and chromatic aberration drastically affect the situation. In addition, certain diffraction defects and scattering impose limitations. These facts and others make it impossible to obtain resolutions near the theoretical maximum. Instead, 2.0 Å is a better theoretical value. Practical limiting resolutions obtained are of the order of 2.5 Å to 3.0 Å .

The basic source of electrons in electronic devices is the heated filament or disc. The well-known equation $J = AT^2 \exp\left(-\frac{\phi}{kT}\right)$ describes the emission, where J is the current density, T is the temperature, ϕ is the work function of the emitting material, A is a constant and k is Boltzmann's constant. J is enhanced by increasing T or reducing ϕ . Typical cathode materials used are tungsten, tantalum, the oxides of barium and strontium, and in certain cases, lanthanum hexabride. A voltage is applied to accelerate the

emitted electrons, and the current density is given by $J = AT^2 \exp\left(-\frac{\phi}{kT}\right)$ if they are all removed to the anode. However, many electrons stay near the cathode and repel other emitted electrons back to the cathode. Most devices operate in this "space-charge limited" way. For any electrode configuration, the current density is then $J = GV$ where V is the applied voltage and G is a constant for the particular electrode configuration. G is roughly equivalent to electrical conductance and is called the "perveance." The constant is fundamentally important. The higher G is in value, the greater is the efficiency of the beam system.

In simple designs, the axial portion of the cathode is overloaded producing excessive emission and cathode burnout. To avoid this situation, carefully shaped electrodes must be used, but the acceptable design depends on the application. A bent hairpin point cathode is used in, for example, the electron microscope. It produces low perveance but high emission density. Since G is low, the field at the cathode can be high, and this tends to reduce ϕ , giving emission at lower temperature. The electron guns for klystrons, traveling wave tubes, and metallurgical applications such as vacuum melting and welding require higher efficiency and current density. Hence they are high-perveance guns.

Electrostatic and magnetic fields control the motion of an electron according to the following equation:

$$\mathbf{F} = m \frac{d\mathbf{v}}{dt} = e[\mathbf{E} + \mathbf{v} \times \mathbf{B}] \quad (3)$$

where \mathbf{F} = force

\mathbf{E} = electrostatic field

\mathbf{B} = magnetic field

\mathbf{v} = electron velocity

e = electronic charge.

The electron must travel in a vacuum if it is not to be scattered and lose its kinetic energy by collision with relatively massive gas molecules. Nuclear particles such as protons and neutrons are each about 1837 times larger in mass than the electron.

Electrostatic Electron Lenses. If in Eq. (3),

$\mathbf{B} = 0$, then $\mathbf{F} = e\mathbf{E}$. The equation says that an electron in a field \mathbf{E} experiences a force \mathbf{F} in the direction of the field. Thus in the system shown in Fig. 1 where there is a voltage V_1 on cylinder 1 and V_2 on cylinder 2 and where $V_2 > V_1$, the field and the path of an electron are as shown. The electron moving from left to right increases its velocity and is deflected towards the axis. After passing the median, the force is away from the axis, but since velocity is increased, the electron spends less time in this part of the field. Therefore, deflection away from the axis is less than it was toward it, and there is a net convergence. If $V_2 < V_1$, as in Fig. 1(b), then for an electron beam traveling from left to right the lens will still be convergent because maximum deflection will occur after the electrons have slowed down. All such lenses are convergent for $E = 0$ on both sides of the lens.

Magnetic Electron Lenses. If in Eq. (3), $\mathbf{E} = 0$ then $\mathbf{F} = e\mathbf{v} \times \mathbf{B}$. This says that the force $\mathbf{F} = e|\mathbf{v}||\mathbf{B}|\sin\theta\mathbf{\hat{e}}$ where $|\mathbf{v}|$ and $|\mathbf{B}|$ are the numerical values of the vectors and θ is the angle between them; $\mathbf{\hat{e}}$ is a unit vector perpendicular to both, and indicates the direction of the force. For \mathbf{F} to be greater than 0, \mathbf{v} must be greater than 0. The force constrains the electron to move in a circle of radius $\rho = \frac{v \sin\theta}{B e/m}$. At the

same time, it moves in a perpendicular direction with velocity $v \cos\theta$ and, therefore, it traces the path of a helix and returns to the axis in a time $T = \frac{2\pi}{B e/m}$ which is independent of both \mathbf{v} and θ .

The net effect is that all electrons are focused by \mathbf{B} to produce an image of the source from which they diverge. Figures 2(a) and 2(b) illustrate a simple magnetic lens which consists of a short coil of wire contained in a surrounding shield of magnetic material. A short gap in the magnetic material concentrates the escaping field when the electromagnet is energized. A spiral distortion of the electron beam results from the use of this sort of lens. For example, in an electron microscope, dual magnetic lenses [Fig. 2(c)] are therefore used. The coils are wound in opposite sense to make distortions cancel. Figure 3 illustrates an electron microscope.

A device worthy of brief consideration is the cathode ray tube. This is used to display voltage wave forms. Its basic components are as follows:

FIG. 1a and b. Electrostatic focusing of electron beam by cylinder lenses (1) and (2).
Fig. 1a, voltage $V_2 > V_1$; Fig. 1b, voltage $V_2 < V_1$.

FIG. 2a. Magnetic focusing of electron beam by solenoid field. Electron path is a spiral as it moves from left to right. Velocity along axis is $V \cos \theta$.

FIG. 2b and c. Magnetic electron lenses. The magnetic field produced by the coil windings is mostly contained in the surrounding shield of magnetic material. The useful volume of the lens is where the field jumps the gap in the shield.

FIG. 3. Schematic diagram illustrating the general arrangement of a transmission electron microscope.

FIG. 4a. Schematic diagram of cathode ray tubes.

an electron gun, an acceleration and focus system, a deflection, and a display system. Figure 4(a) shows the construction. Depending on the type of tube, the applied voltage generates an electrostatic or magnetic field, and the field deflects a beam of electrons on its path to a fluorescent screen. The deflection is proportional to the voltage. In the television tube, the beam is deflected to trace each part of the screen in sequence. At the same time it is intensity modulated, enabling the picture to be constructed of dark and light elements. Magnetic deflection is used in this case because large scan angles are required.

Electrostatic Deflection. If in Fig. 4(b) a voltage V_d exists between the plates x_1x_2 and an electron enters along the axis with a constant velocity $v = (2Ve/m)^{1/2}$, then because of the field E_y caused by V_d , a transverse force F_y causes a

FIG. 4b. Deflection of electron beam by electric field between parallel plates X_1X_2 .

motion in this direction to be impinged on the electron, i.e., $m \frac{d^2y}{dt^2} = \frac{V_a e}{d}$, from which $\frac{dy}{dt} = \frac{V_a e}{d} t$ and $y = \frac{1}{2} \frac{V_a e}{d} t^2$. The force acts for time $t = \frac{l}{v}$; thus deflection $y = \frac{1}{2} \frac{V_a e}{d} m \left(\frac{l}{v} \right)^2 = \frac{1}{4} \frac{V_a l^2}{d} \frac{1}{v}$. The additional deflection, after F has ceased to act on the electron, is $y' = \frac{V_a l L}{V} \frac{1}{2d}$.

Magnetic Deflection. See Fig. 4(c). If B is a sharply defined field, then the deflection on leaving the field is given by $y = \frac{l^2}{2\rho}$. Total deflection $= D - L \tan \alpha + y$. To a good approximation $D = \frac{BLl}{v} \frac{e}{m} \left(1 + \frac{l}{2L} \right)$.

FIG. 4c. Deflection of electron beam by magnetic field. Electron path is an arc of a circle only while it is influenced by field. After leaving the field the path is linear.

It should be emphasized that these considerations are only approximate. In practice, factors such as the inability to sharply define a field edge in space cause added complications.

ELECTRON SPIN

The electron is an elementary particle of essential importance to atomic physics and, in addition to its stability, basic charge e , and small rest mass m , it has been found to possess a quantum mechanical attribute named "spin." As the name implies, this is a mechanical angular momentum of fixed magnitude (projected) of $\frac{1}{2}h$ (one half Planck's constant divided by $2\pi = 0.52722 \cdot 10^{-31}$ joule-second). Intimately associated with this intrinsic quantized angular momentum is a magnetic moment of approximate value $eh/2m$ (this quantity is called the *Bohr magneton*, μ_B , and has the value $0.92732 \cdot 10^{-23}$, ampere-meter²). While these concepts have a classical analogy in an imagined spinning or rotational motion of the charge and mass of the electron (assumed to be not a point), nevertheless, it is not possible to treat the electron spin wholly classically. For instance, the electron *gyromagnetic ratio* (ratio of the magnetic moment to the mechanical moment) is twice the classical value. Also, since the spin quantum number is limited to $\frac{1}{2}$, the spin disappears in the classical limit of $h \rightarrow 0$. The fact that these properties are quantized implies their quantum nature, and indeed, the spin and magnetic moment are natural consequences of the relativistically invariant Dirac equation.

The hypothesis of the electron spin was first proposed in 1925 by Uhlenbeck and Goudsmit to explain the spectroscopic fine structure. The spin can be introduced as a vector S such that the square of the spin has the eigenvalue $S \cdot S = s(s+1)h^2$ where $s = \frac{1}{2}$ so that $S = \sqrt{\frac{3}{4}}h$. The component of S in a specified direction, such as the z axis, is $S_z = mh$ where $m_s = +\frac{1}{2}$ or $-\frac{1}{2}$. This implies a spin angular momentum component of absolute value $\frac{1}{2}h$. It is further necessary to postulate that the intrinsic magnetic moment of the electron (due to its spin) is $\mu = -e/mS$. The component of μ along the z axis is then $\mu_z = m_s(eh/m)$ or $\pm \mu_B = \mu_B$.

Direct experimental evidence for quantized electron angular momentum and magnetic moment was presented by the Stern-Gerlach experiment in 1922. A collimated beam of neutral silver atoms was directed through an inhomogeneous magnetic field. This field acted on the magnetic moment of the unpaired valence electron of the silver atom to produce a transverse force and, hence, a lateral deflection. In contrast to the classical expectation of a continuous spread of deflections due to many possible orientations of the electron magnetic moment, it was observed that only two opposite deflections occurred. This implied only two possible values for μ_z leading to the space quantization of spin, $m_s = \pm \frac{1}{2}$. Similar molecular beams have provided Rabi and Kusch and their colleagues with a

supply of free atoms and molecules whose orientation in magnetic fields could be varied with magnetic resonance. Considerable information on atomic hyperfine structure has resulted from these measurements as well as recognition of the anomalous magnetic moment of the electron.

It had been thought that the magnetic moment of the *free* electron could not be directly measured due to the overwhelming force associated with the motion of the charge in the magnetic field. However, Crane and his colleagues have trapped electrons into helical orbits in a magnetic field and have accurately compared the cyclotron orbital frequency to the spin precessional frequency. This makes possible a highly precise measurement of the *electron magnetic moment* and its value was found to be slightly larger than a Bohr magneton, $\mu_e = 1.001159622 \mu_B$. This anomaly is now understood as a consequence of the uncertainty jittering or pulsation in which the electron exchanges virtual photons with the radiation field and experiences a sort of radiation reaction which increases its effective inertial mass. The spinning motion should not be affected by this change and, hence, the magnetic moment should be slightly greater when measured in units of Bohr magnetons using the apparent inertial mass of the electrons. The theory has been worked out in adequate detail and the electron magnetic moment is predicted to be $\mu_e = \mu_B(1 + \alpha/2\pi - 0.327\alpha^2/\pi^2)$ in good agreement with experiment. This more precise value is 0.92839×10^{-23} ampere-meter².

An important consequence of the spin concept occurs when the Pauli exclusion principle is applied to polyelectronic atoms using the spin quantum number $m_s = \pm \frac{1}{2}$ in addition to the principle quantum number n , the azimuthal quantum number $l \leq n - 1$, and its projection $m_l \leq l$. The Pauli exclusion principle; based on the symmetry properties of the wave functions appropriate to the electron as a Fermi particle (i.e., spin $\frac{1}{2}$ particle), limits the number of electrons in an atom to those which can be differentiated by unique sets of quantum numbers. The possible combinations of the integral quantum numbers n, l, m_l with the two possible values of m_s determine the number and structure of the electrons in the atom. The recurring similarities in the orbital characteristics of the outer electrons produced by the quantum numbers determine the valencies and chemical characteristics of the atoms in a periodic fashion as exemplified in the periodic table.

Since the electron spin can have two orientations with respect to the axis of the orbital motion of the electron, a difference in energy will result from the interaction of the spin magnetic moment with the magnetic field produced by the orbital motion. This energy difference can be evaluated and leads to a *fine structure separation energy* which is less than the electronic level separations by a factor of the order of α^2 where $\alpha = e^2/4\pi\epsilon_0\hbar c$ is the fine structure constant, approximately $1/137$. This is the origin of the well-known sodium yellow doublet.

The imposition of an external magnetic field gives rise to further splittings called *Zeeman effects*. The spin couples with the orbital motion giving rise to *splitting factors*, g , which are complicated because of the different gyromagnetic ratios of the spin and orbital motions. If the magnetic field is strong enough, it can uncouple the spin from the orbital motion giving a somewhat simpler Zeeman splitting called the complete Paschen-Back effect.

The magnetic effects of the electron's spin magnetic moment as well as their orbital moment are reduced by the tendency of electrons in atoms to pair spins of opposite direction and to complete shells of compensating orbital motion. This is even more pronounced in molecules since the chemical binding force is essentially the result of pairing electrons and completing shells. Nevertheless, when an unpaired electron exists, its magnetic moment is available for detection and can be measured by determining the aggregate magnetic moment of the sample. However, a more sensitive method, with considerably better accuracy and resolution, involves a magnetic resonance measurement (see MAGNETIC RESONANCE). When applied to the electron spin magnetic moment the measurement is often called ESR, or *electron spin resonance*, but more widely, EPR, or *electron paramagnetic resonance*. These techniques extend the earlier atomic and molecular beam resonance measurements of Rabi and his school.

The detection can be described, quantum mechanically, in terms of the absorption of photons of frequency f and photon quantum energy hf by excitation of transitions between neighboring quantum states of the atom or molecule separated by the Zeeman splitting due to an imposed external magnetic field. Since the energy difference is primarily $g\mu_B B = hf$, the frequency for reasonable fields of the order of a thousand gauss (i.e., $B \approx 0.1$ weber/m²) is in the microwave region, i.e., $f \approx 10^{10}$ cps. Consequently, the techniques appropriate to these measurements are associated with microwave spectroscopy.

The simplest cases are those in which the odd electrons are in *S* states with no orbital motion, or in which the magnetic effect of the orbital motion is "quenched" by the presence of neighboring atoms. Then, "spin-only" effects occur and the splitting factor g is close to 2. When quenching does not occur, the orbital motion magnetic field complicates the Zeeman splittings and gives rise to more complex patterns of resonance. In solids, the crystalline electric field affects the orbital motion and, hence, the pattern which then varies with crystal orientation. Interaction of the electron magnetic moments with the nuclear magnetic moments gives hyperfine splittings with even greater detail.

A large number of atoms which show paramagnetic or electron spin effects are those in the transition groups, i.e., iron group, rare earth, palladium group, platinum group and actinide group in which inner electron shells are being filled.

Other situations where the electron magnetic moment effects are useful for analysis or detection include free radicals, molecules with broken bands from irradiation or heating, etc., conduction electrons in some metals, and defects and impurities in crystals.

In solids composed of elements of the iron group (occasionally the rare earths), the long-range cooperative effects between electron spin magnetic moments give rise to ferro-, ferri-, and antiferromagnetism.

ELECTRON TUBES, RECEIVING TYPE

An electron tube consists of a heater for kinetic energy excitation of electrons, a cathode which acts as a transfer electrode source of electrons, controlling grid electrodes, and an anode that is maintained electrically positive with respect to the cathode. These elements are insulated from each other and enclosed within an evacuated envelope made of either glass, metal, ceramic, or a combination of these materials. A getter is flashed within the tube to absorb any residual gas molecules which could have a harmful effect—electrically and chemically—on the operation of the tube.

When the device has only two electrodes, a

cathode and an anode, it is called a *diode*. With the anode maintained electrically positive with respect to the cathode, an electric field results which causes the electrons to move toward the anode. In the external circuit, the electrons flow from the anode through the load impedance and then through the voltage source to the cathode, which acts as a low-work-function transfer medium, and so back to the anode. In this discussion, the work function is considered to be the total amount of work necessary to free an electron from a solid.

Other electrodes are often introduced between the cathode and the anode in the form of grids. By varying the voltages on these intervening electrodes, it is possible to modify the electric field between the cathode and the anode, and thus to control the current in the external circuit. Tubes having one grid in addition to the cathode and anode are called *triodes*. Tubes with two grids are called *tetrodes*; tubes with three grids are called *pentodes*. In general, tubes are labeled in accordance with the total number of active electrodes in a linear arrangement using a common electron stream. Sometimes, two or more sections are enclosed within the same envelope (e.g., a diode-triode or a triode-pentode); these tubes are not referred to in terms of the total multi-electrode structure, but they are designated in terms of the respective tube units.

FIG. 1.

FIG. 2. Structure of a miniature tube.

Oxide-coated Cathode. Oxide-coated filamentary cathodes can operate at relatively low temperatures of 1000°K because of the low-work-function surface layer. However, they are subject to sputter effects and can also evaporate substantial amounts of material that deposit onto adjoining electrodes and lead to harmful grid-emission and contact-potential phenomena. Such oxide-coated filaments are high-efficiency emitters at low-wattage inputs and are used successfully in low-current pulsed high-voltage rectifiers for scanning systems in television receivers.

The indirectly heated cathode consists of a nickel alloy sleeve coated with alkali earth oxides of barium and strontium, and, inside the sleeve, a heater of alumina-coated tungsten or molybdenum-tungsten alloy wire. The heater wire is in the form of a helical coil or folded strands; it is coated with alumina to insulate the heater wire from the cathode nickel sleeve. In addition this insulating coating prevents adjoining helix turns or strands of wire from short-circuiting each other. The cathode sleeve is heated by conduction

and radiation from the heater. Because the oxide-coated cathode is electrically isolated from the heater, it is called a *unipotential cathode*, since unlike the filamentary type, there is no voltage drop along its length due to heater current.

The use of the indirectly heated unipotential cathode offers two advantages. The nickel-alloy sleeve acts as a magnetic shield around the heater wire and minimizes the effects of 60-cycle hum from the ac heater supply. Secondly, the use of separate heater and cathode circuits permits the design of close-spaced control grids and cathodes which in turn result in higher gain amplifier service. In addition, the use of close cathode-to-anode spacing design in rectifier service creates low tube-voltage drops and better voltage regulation.

Because of these advantages, electron tube manufacturers make extensive use of the indirectly heated cathode system. The oxide coating formed on the nickel-alloy cathode is derived from alkaline earth carbonates, either 50/50 mole per cent barium-strontium carbonate or 49/45/6 mole per cent barium-strontium-calcium carbonate. The presence of this activated oxide coating lowers the work function of the substrate nickel.

The electron emission performance of the indirectly heated cathode is influenced by three basic factors: (1) the effects of the low work function, (2) an *n*-type semiconductor method of electron transfer, and (3) the electron transfer efficiency involved in the porous nature of the alkaline earth oxide matrix coating. These three factors are discussed in the following paragraphs.

The work function ϕ of a material is measured in electron volts and is temperature dependent. Such temperature dependence can be influenced by the work function of the substrate metal or by adsorbed layers of atomic films. When atoms having a lower work function are adsorbed onto the surface of a metal having a higher work function, the work function of the substrate metal is reduced by the decrease in its surface energy potential barrier. For example, when a monolayer of barium ($\phi = 2.52 \text{ eV}$) is adsorbed on the surface of nickel ($\phi = 4.96 \text{ eV}$), the resultant adsorption layer of barium-oxygen-nickel has a work function $\phi = 0.9 \text{ eV}$.

The usefulness of materials having low work functions is limited by their high rate of evaporation which tends to deposit material onto adjoining electrodes as well as to shorten the life of the system under vacuum-tube conditions. Accordingly, balance of work function and rate of evaporation is a desired feature in effective cathode design. The barium/barium oxide component of the alkaline earth oxide matrix meets this requirement by having the lowest usable work function consistent with a minimum rate of evaporation and long life at the operating temperature (1025°K) of such cathode systems.

Normally, barium oxide is an insulator. In vacuum-tube technology, however, the oxide is made to act as a semiconductor material by an activating process which uses physical chemical reactions to form barium and associated donor

FIG. 3. Parts of a Novar Tube.

sites in the oxide lattice. In addition to having a low work function, the barium oxide now exhibits properties similar to an *n*-type semiconductor which allows it to transfer electrons at temperatures below 575°K. Furthermore, a relatively thick oxide coating of 0.5 to 2.0 mil thickness will result in favorable coating porosity and electron pore gas transfer at temperatures above 575°K. Although electron pore gas transfer does not reduce the work function of the system, it does improve the conductivity of the oxide layer at 1025°K. The resulting decrease in voltage drop across the oxide coating reduces the potential minimum and improves the emission performance.

Barium and the associated donor centers are

produced by the chemical reduction of barium oxide by elemental agents of carbon, magnesium, silicon, and tungsten present within the cathode nickel alloy. This reproductive action is a function of the effective concentration of the elements, as well as their rate of diffusion through the metal, and their rate of reaction with the emission oxides at the interface region.

In conclusion, the operating characteristics of the oxide cathode system itself are determined by a number of physical chemical factors including: the porosity of the applied coating; the conversion of the carbonates to the oxide crystal lattice form; the minimum sintering action induced by the eutectic phase of barium carbonate/barium oxide; the rate of electrolytic transport

of the barium ions; the evolution of oxygen gas; the rate of evaporation of barium/barium oxide; and the formation of films on adjoining electrodes. Thus, the oxide-coated cathode system operates in a dynamic equilibrium involving solid, ion, and gas phase changes across the interface region of the cathode metal-to-oxide layer as well as the phase boundary between the oxide layer and the residual gases and vapors in the vacuum regions of the tube. These equilibria are dependent upon the noninjurious trace concentrations of carbon dioxide, oxygen, water vapor, sulfur, halogens, and volatile metal oxides in the environmental vacuum region for the best electron transfer performance and long life of the cathode system.

Diodes. As previously mentioned, the diode is the simplest form of vacuum tube having a cathode system and anode together with a flashed getter. In well-degassed tube structures, the reducing element content of the cathode nickel alloy creates sufficient active barium sites in the emission oxide matrix so that the unit itself can function as a getter at high operating temperatures. Diodes are used as rectifiers, detectors, dampers, and limiters. These tubes are high-vacuum types in which the internal voltage drop is proportional to the dc load current. When a low constant-voltage drop is desired, mercury vapor tubes are used. The constant-voltage drop of 15 volts is a function of the ionization potential of the mercury vapor since the positively charged mercury ions neutralize the space charge effect. In general, for diodes, when the current demand is less than the temperature-limited value, the current I will vary as the three-halves power of the applied voltage E as given by the following equations. For the plane parallel system: $I = (2.33 \times 10^{-6} E^{3/2}) S^2$ where S is the cathode-to-anode spacing. For the concentric cylindrical system: $I = (14.65 \times 10^{-6} E^{3/2}) (h^2 \times r_a)$ where h is the ratio of the anode radius r_a to the cathode radius r_c . For very low anode voltages, the above approximations are not accurate because the effects of the initial electron velocity and the contact potential result in currents larger than calculated.

Not all electrons leaving the cathode reach the anode. Some electrons return to the cathode by reason of a balance between the initial electron velocity and the image force; i.e., when an electron is emitted from a metal surface and is at some distance from the surface, it induces a charge of equal magnitude but opposite sign in the interior of the metal. As a result, some electrons remain in the space above the cathode and produce a cloud of electrons or "space charge" which repels some electrons back to the cathode and thus impedes the flow of electrons to the anode. The extent of this action and the amount of the space charge are dependent upon the temperature of the cathode, the cathode-to-anode spacing, and the anode potential.

Under fixed temperature conditions, the maximum number of electrons that are emitted is also fixed. The higher the anode potential, how-

ever, the lower is the number of electrons remaining in the space charge region; as a result, an increase of the anode voltage results in an increase in current until saturation is reached. Beyond this condition (maximum current at maximum voltage at fixed cathode temperature conditions), additional anode (plate) voltage will only increase the plate current slightly because of the reduction of the work function at the cathode due to the electrostatic effect of the applied field.

The Richardson-Dushman equation yields information pertaining to the work function ϕ of cathode systems and the zero field saturated current I_{s0} with respect to temperature T . The emission equation for a cathode of surface area

S has the form $I_{s0} = A_0 S T^2 e^{-\frac{11610 \phi_0}{T}}$. The zero field saturated current I_{s0} is extrapolated from a plot of the log I_s (saturated current) as a function of the square root of the applied voltage at the anode V_a . The work function with an external field E is a function of the square root of the external field strength such that $\phi_E = \phi_0 - 3.78 \times 10^{-5} E^{1/2}$.

Triode. When a third electrode, called a grid, is placed between the cathode and the anode, the tube is called a triode. This grid consists of a fine wire wound on two support side rods; the spacing between the turns of the wire is relatively large so that electrons are able to pass from the cathode to the anode. When the tube is used as an amplifier, a varying signal imposed on a negative dc voltage on the grid controls the plate current. As the grid voltage becomes more negative, the plate current decreases while the plate voltage increases back to the original applied potential as a result of the decrease in the voltage drop across the load impedance. In other words, the grid voltage and the plate current are in phase, but the plate voltage is 180° out of phase with the grid voltage. The cathode, grid, and plate of the triode form an *electrostatic system* such that it is possible to equate the plate current I_b to a three-halves power law similar to that for diodes, i.e.,

$$I_b = K \left[\frac{C_{gk}}{C_{pk}} \cdot E_g + E_b \right]^{3/2}$$

where K is a constant (the permeance) which depends upon the geometry of the tube, and C_{gk} and C_{pk} are the grid-to-cathode and the plate-to-cathode capacitance, respectively. This equation assumes a negligible effect for the initial velocity of electrons from the cathode. Actually, the initial electron velocity creates the space-charge effect so that the cathode is slightly negative (instead of zero) and a potential minimum exists a short distance in front of the cathode. The effect of this shift is to increase the plate current slightly. Because the initial electron velocity distribution depends upon cathode temperature, the plate current will also be influenced by the cathode temperature even though it is limited by the space charge.

The electrical characteristics of triodes are described in terms of three parameters: the amplification factor (μ), the dynamic plate resistance (r_p), and the transconductance (g_m) as given by the following relationships:

$$\mu = \frac{C_{pk}}{C_{pk}} = \frac{\partial e_b}{\partial e_g} = - \frac{de_b}{de_g} \Big|_{i_b \text{ constant}}$$

$$r_p = \frac{\partial e_b}{\partial i_b} = \frac{de_b}{di_b} \Big|_{e_g \text{ constant}}$$

$$g_m = \frac{\partial i_b}{\partial e_b} = \frac{di_b}{de_b} \Big|_{e_g \text{ constant}}$$

These relationships are applicable within the region where the family of curves is straight, parallel, and equidistant for equal increments in the parameter. The triode tube can be considered a linear circuit element within small variations, and the quantities μ , r_p , g_m may be used as constants in the analysis of tube performance. A useful approximation for the calculation of plate current I_b is the expression

$$I_b = \frac{2.33 \cdot 10^{-6} (E_g + E_b/\mu)^{3/2}}{(S_{rk})^2} \quad \text{or} \quad I_b = \frac{2.33 \cdot 10^{-6} \left(E_g + \frac{E_b}{\mu} \right)^{3/2}}{(S_{rp})^2/\mu}$$

where S is the distance between grid-to-cathode and grid-to-plate, respectively and

$$\mu = \frac{g_m E_g}{3/2 I_b - g_m E_g}$$

Tetrodes. The effects of interelectrode capacitances between the grid and the plate and between the grid and the cathode sometimes result in coupling between the input and output circuits. Such coupling and impedance mismatching can cause instability and low output performance. The grid-to-plate capacitance can be sufficiently reduced by the introduction of an additional grid electrode, called the screen grid, between the control grid and the plate, and such tubes are known as tetrodes. In practice, the control grid-to-plate capacitance is reduced from several picofarads for a triode to less than 0.01 pF for a screen grid tube when a rf capacitor is connected between the screen grid circuit and the cathode.

The screen grid operates at a positive voltage and supplies an electrostatic force which pulls electrons from the space charge region, through its widely spaced turns of wire, and onto the plate. The plate is shielded from the cathode and exerts insignificant force on the space charge region. The plate current in a tetrode is almost independent of the plate voltage and depends mainly upon the screen grid voltage. With tetrodes, moderately high amplification can be obtained without capacitive feedback from the plate to the control grid. However, for operation

in amplifiers where linearity is required between the control grid voltage and the plate current, the transconductance must be constant. To achieve this condition, the tetrode must be operated in the region where the plate voltage is higher than the screen voltage, i.e., where the family of curves is nearly straight, parallel, and equidistant for equal increments.

Tetrodes are not useful for amplification of very large signals because the proximity of the positive screen grid to the plate (at equal or slightly higher positive voltage) permits the capture of secondary electrons emitted from the plate. The capture of the lower-velocity secondary electrons by the screen grid is more pronounced when the plate voltage swings lower than the screen grid voltage. This condition occurs when large signal variations cause an increased voltage drop across the load impedance in the plate circuit.

Pentodes. The effects of secondary emission from the plate in a tetrode configuration are minimized when a fifth electrode is used. This fifth electrode (a third grid) is made of widely spaced turns of wire between the screen grid and the plate, and is known as the *suppressor grid*; it is usually connected to the cathode at zero potential. A tube with five electrodes in a linear arrangement, a cathode, three grids, and a plate, is called a pentode. The suppressor grid is negative with respect to the plate and can divert secondary electrons of low velocity back to the plate. Pentodes are capable of high voltage amplification and high power output at low levels of driving voltage on the control grid. When large signal inputs are placed on the control grid, large load impedance voltage drops result in the plate circuit which cause the plate voltage to become momentarily lower than the screen grid voltage without the loss of secondary electrons from the plate.

Instead of a suppressor grid, the interelectrode region between the screen grid and the plate can be virtually used as a space charge region to minimize the loss of secondary electrons from the plate. In practice, a suppressor grid or a beam-confining plate is used to enhance the effect of the electron cloud density. This effect is created primarily by designing the tube electrodes in such a way that the electron stream from the cathode is confined and concentrated in the region between the screen grid and the plate. The space potential is depressed at some point in the interelectrode region in front of the anode to a value below the anode potential to prevent secondary electrons from reaching the screen grid. A tube with this feature of construction is called a *beam-power tube*.

In beam-power tubes, the pitches of the helical turns of the lateral wire of the control grid and the screen grid are made equal and the wires are aligned to confine the passage of electrons into flat beams. A focusing beam plate, or optional use of a wide-spaced suppressor grid electrode, is used to maintain this high electron density. Because of the alignment of the control grid and

the screen grid, very few electrons are captured by the screen grid; thus, a beam power tube draws low current in the screen grid circuit. Effective suppressor grid action and low screen grid current permit beam power tubes of moderate size and voltages to operate efficiently at high power outputs with large values of transconductance. The large values of transconductances obtained with beam power tubes make them useful in the design of wide-band amplifiers for television service.

In both tetrodes and pentodes, the control grid is sometimes constructed in a non-uniform manner. The spacing between the adjoining helix turns of the grid lateral wire is made closer at the ends than at the center of the grid. In tubes with such variable pitch grids, the amplification factor decreases when the plate current decreases. Such grid structures also require large negative voltages to produce cut off conditions. These tube types are known as remote cutoff or variable- μ tubes. Tubes having uniform grids are called sharp cutoff tubes. Remote cutoff tubes are used in automatic-volume-control circuits in which the dc component of the control grid voltage is varied in such a manner that the amplification of the tube is made smaller for large signal voltages.

Multifunction Tubes. In addition to the single function multigrid tube such as a tetrode amplifier 6CY5 or a pentode amplifier 6BC5, there are other multi-electrode tubes that perform more than one function, e.g., an oscillator and mixer in a superheterodyne receiver. The term pentagrid converter represents a tube with five grid structures that lie in the electron stream between the cathode and the plate. Two of the grids function as control grids; the remaining grids function as screen or suppressor grids to shield the control grids from the plate, e.g., pentagrid converters 6BE6 and 6SA7 or the 6BY6, a pentagrid amplifier used in color television receivers as a sync separator and sync clipper as part of a gated amplifier circuit.

There are also multi-unit tubes consisting of combinations of diodes, triodes and pentodes in one envelope which use more than one cathode and/or plate. For example, the twin triode 12AX7A used in resistance coupled amplifiers; the 8AW8A in which the triode unit is used in a sync separator circuit and the pentode unit is used as an i.f. or video amplifier; and the triple triode 6EZ8 used in oscillator mixer and AFC circuits in FM receivers.

Microwave. The above mentioned multigrid and multi-unit tubes normally are used in amplification circuits at frequencies up to 500 Mc. However, above this frequency range, the transit time of electrons is short when compared to the voltage cycle and, as a result, the phase angle between the plate current and the plate voltage becomes less than 180° . Accordingly, an increase occurs in the power dissipated at the plate for a given designed power output. At these very high frequencies, electron loading can occur at the control grid because of the short transit time of the electrons from the cathode to the plate.

Certain pencil triode tubes are made to operate in the 500-Mc region with regular tube constructional arrangement except that the interelectrode spacing between cathode and grid, and between grid and plate, is made very small—about 1-mil clearance—in order to accommodate the short transit time of electrons.

To avoid the difficulties resulting from the short transit time of electrons as well as the effects of interelectrode capacitances, microwave tubes have been designed to make use of velocity-modulated beams of electrons. Klystrons, traveling-wave tubes, and magnetrons are special-purpose tubes designed to operate in the microwave region.

ELECTRONICS

The term "electronics" (Ger. *Elektronik*) was first used to describe the branch of physics now generally called physical electronics; that usage goes back almost to the discovery of the electron in 1897, as witness the names of two early journals in the field, *Jahrbuch der Radioaktivität und Elektronik* (founded in 1904) and *Ion: A Journal of Electronics, Atomistics, Ionology, Radioactivity and Raumchemistry* (1908).

In the currently prevalent technological context, the adjective "electronic" and the noun "electronics" (Ger. *technische Elektronik*) date back only to the 1920's and did not achieve wide circulation until after the foundation of the journal *Electronics* by McGraw-Hill Publishing Co. in 1930. (The older meaning also survives: as an example, the Institute of Physics and Physical Society in Britain has an Electronics Group concerned with physical electronics.)

Electronics in the technological sense has been variously subdivided into categories that encompass most of the profession of electrical engineering. For instance, when the American Institute of Electrical Engineers and the Institute of Radio Engineers combined in 1962 to form the Institute of Electrical and Electronics Engineers, the new

organization comprised 34 specialized groups, most of them pertaining to electronics, as follows:

Aero-Space	Geoscience Electronics
Aerospace and	Human Factors in
Navigational	Electronics
Electronics	Industrial Electronics
Antennas and	and Control Instru-
Propagation	mentation
Audio	Industry and General
Automatic Control	Applications
Biomedical Engineer-	Information Theory
ing	Instrumentation and
Broadcast and Tele-	Measurement
vision Receivers	Magnetics
Broadcasting	Microwave Theory
Circuit Theory	and Techniques
Communication	Military Electronics
Technology	Nuclear Science
Component Parts	Power
Computer	Product Engineering
Education	and Production
Electrical Insulation	Reliability
Electromagnetic	Sonics and Ultrasonics
Compatibility	Space Electronics and
Electron Devices	Telemetry
Engineering Manage-	Vehicular Communica-
ment	tions
Engineering Writing	
and Speech	

Such grouping points up the increasing penetration of electronics into various branches of technology and science, a process that is by no means as yet complete. Few educated people remain unaware of the role that electronics has played not only in the communications industry and in the development of computers (both with regard to military and to space applications), but also in industrial instrumentation and control (automation). Less generally appreciated is the part that electronics is coming to play in such diverse fields as food technology, geophysical exploration, medical instrumentation, materials processing, and a host of other endeavors not usually associated with electronics.

Research scientists depend on electronics *qua* technology to a surprisingly large extent. Many of the scientist's conventional instruments have been replaced by electronic devices of greater capabilities. Even more important, the advent of electronics has sparked the development of entire new branches of science such as microwave spectroscopy, electron microscopy, radio astronomy, and other fields that depend on processes such as amplifying weak signals; transmitting, recording, and analyzing large amounts of rapidly acquired data at high rates; and investigating phenomena at frequencies extending from the audio to the visible range.

Electronics is certainly repaying its large debt to physics, in numerous ways. Not only have cathode-ray oscilloscopes, vacuum tubes, and scintillation counters been joined by transistors

and other semiconductor devices to provide an ever-increasing range of complex instruments, but the very devices that have been developed as a result of certain discoveries in physics have, in turn, been used in physics research in a very direct way. A few instances will suffice to illustrate the point.

Discovery of the physical phenomenon of secondary emission of electrons has led to the development of the *photomultiplier*, an instrument that has revolutionized nuclear physics by its ability to enhance otherwise imperceptible signals and to make it possible to register extremely large numbers of discrete events.

Photoelectronic *image intensifiers*, developed in the first instance for television camera tubes, have found application in astronomy, to increase the efficiency of optical instruments and to detect faint objects against relatively bright backgrounds; in nuclear physics, to record the passage of fast nuclear particles through transparent phosphor blocks and perhaps to detect Čerenkov radiation from fast particles passing through a dense medium; in spectroscopy, to enhance ultraviolet radiation that could be otherwise detected through glass or quartz windows only with difficulty; and in the detection of x-ray patterns, both where it is necessary to detect radiation down to the shot-noise level of the x-ray quanta and in medical radiology, where the patient must be protected from excessive dosage. The applications related to nuclear physics depend on a further property of the device—its ability to be switched on or off within nanoseconds, so that one specific event out of a multitude of uninteresting events can be recorded.

The high-resolution *electron spectrometer*, derived from the electron microscope (which in turn is a descendant of the cathode-ray tube), has been used to investigate the characteristic losses of electrons transmitted through thin films of metals and alloys, providing information of basic importance for metallurgy.

Various physical principles of importance to electronics, and the corresponding devices, are described elsewhere in this book. Additional information on electronics is available in the writer's "The Encyclopedia of Electronics" (Reinhold 1962), a companion volume to the present work.

ELEMENTARY PARTICLES

The search for the elementary constituents of matter is as old as physics itself, but any quantitative attempt at such a theory had to await the experimental discoveries of this century. Such a search is prompted by two considerations: the identification of the basic building blocks of nature and the hope that their laws of interaction would be essentially simple.

The atom had to yield its claim to be indivisible when it was found that electrons were constituents of all atoms; moreover, the electrons from various species of atoms were identical. Light, with its particle properties, seemed another universal entity connected with matter, since the photons (light quanta) which were emitted in atomic transitions appeared identical apart from their momenta. The electron and the photon were the first two elementary particles to be discovered, and a quantitative theory of the emission and absorption of photons by the electrons in an atom was possible only after the invention of quantum mechanics. The corresponding picture of the atom regarded the electrons in an atom as being subject to electrostatic attraction of the positively charged nucleus (and the mutual repulsion of the electrons), the photons having only a transitory existence being either emitted or absorbed in the transitions between the atomic states. The search for the structure of matter now became a search for the constituents of the nucleus.

A quantum theory of the nucleus (or rather nuclei) was made possible by the discovery of the proton and the neutron. The nuclear interaction which was responsible for holding the nucleus together (against the disruptive electrostatic repulsion of the protons) was found to be of an entirely new kind, much stronger than the electric interaction at short distances but decreasing very much more rapidly with distance. The various complex nuclei differ in the number of protons and neutrons they contain.

By that time, the theory of the interaction between electrons and photons had developed to the point where the electrostatic repulsion or attraction between electrically charged particles could be understood in terms of the exchange of photons between them. In the lowest nontrivial approximation, it gave the Coulomb law for small velocities. The basic interaction was the emission and absorption of "virtual" photons by charged particles. A similar mechanism could be invoked to explain the short-range nuclear interaction; and essentially our present picture of the nuclear interaction is that it is due to the exchange of particles, which have nonzero masses which are a fraction of nuclear mass—the same approximation procedure used for deducing the static Coulomb force (from the electron-photon interaction) is no longer valid here; and the nuclear force has a rather complicated form. However, these theoretical considerations did predict the existence of a set of three particles called pions, which have since been discovered.

Another kind of particle and another kind of

interaction were discovered from a detailed study of beta radioactivity in which electrons with a continuous spectrum of energies are emitted by an unstable nucleus. The interactions could be viewed as being due to the virtual transmutation of a neutron into a proton, an electron and a new neutral particle of vanishing mass called the neutrino. The theory provided such a successful systematization of beta decay data for several nuclei that the existence of the neutrino was "well-established" more than twenty years before its experimental discovery. The beta decay interaction was very weak even compared to the electron-photon interaction.

Meanwhile, the electron was found to have a positively charged counterpart called the positron; the electron and positron could annihilate each other, with the emission of light quanta. The theory of the electron did in fact "predict" the existence of such a particle. It has, since then, been found that the existence of such "opposite" particles (antiparticles) is a much more general phenomenon (see below).

Our present catalog of elementary particles and decay modes contains many more entries. These particles fall into five families: the photon family, the electron family, the muon family, the meson family and the baryon family. Most of these particles are unstable and decay within a time which is often very small by normal standards but which is many orders of magnitude larger than the time required for any of these particles to traverse a typical nuclear dimension. There is a wide variety of reactions between them, but they could be understood in terms of three basic interactions—the strong (or nuclear) interaction⁵, the electromagnetic interactions and the weak interactions. The nuclear forces and the interaction between pions and nucleons belong to the first, the electron-electron and electron-photon interactions to the second, and the beta decay interaction to the third. The present theoretical framework enables us to handle more or less quantitatively the electromagnetic and weak interactions only. Despite this, it is possible to understand many aspects of strong (as well as the other) interactions in terms of conservation laws and invariance principles (see CONSERVATION LAWS AND SYMMETRY).

The classical conservation laws of energy, momentum and angular momentum are valid in the relativistic quantum theory of elementary particles also. The particles may possess intrinsic angular momentum or "spin" which expressed in natural units $\frac{h}{2\pi}$ of angular momentum is restricted to an integer or a half-odd integer. Angular momentum conservation holds only when this spin angular momentum is included. But one finds that to every particle, there corresponds an antiparticle with the same mass, same spin and same lifetime. (In the case of the photon and the neutral pion, they are their own antiparticles; they are strictly neutral particles.) The particle and antiparticle have equal and opposite electric

charges, and the antiparticle of the antiparticle is the original particle. The conservation of electric charge is another familiar (although non-classical) conservation law satisfied by all known interactions. It is the prototype of a set of "additive" conservational laws which include the conservation of the baryon number, the muon number and the electron number. To the best of our knowledge, these conservation laws are still exact.

In addition to these additive conservation laws which arise from continuous symmetries, there are a set of "multiplicative" conservation laws which are associated with discrete symmetries. It is possible to examine the invariance of the physical laws under space inversion, i.e., using a left-handed coordinate system instead of a right-handed coordinate system or vice versa; if the statement of the law is unaffected by this interchange, it is possible to show that a quantum number having the two values ± 1 can be assigned to classify the quantum-mechanical states such that a state with the label $+1$ will not change to one with the label -1 due to any interaction. This quantum number is called "parity." Just as particles may possess intrinsic angular momentum (spin), particles may also have intrinsic parity. Table I lists the particles (and their corresponding antiparticles) with their respective additive quantum numbers, intrinsic parities and lifetimes. General principles of relativistic quantum theory imply that antiparticles of integral spin particles have the same parity as the particles; for half-odd-integral spin particles the antiparticle has the parity opposite that of the particle. All experimental checks are in accordance with this prediction.

In addition to invariance under space inversion, we may consider particle conjugation (replacement of particles by antiparticles), invariance, and time reversal invariance, or combinations of these transformations. It turns out that strong and electromagnetic interactions are invariant under each of these three transformations (and hence any product of these), but weak interactions are invariant only under combined inversion (product of particle conjugation and space inversion) and under time reversal. It can be shown that all interactions are invariant under the product of the three transformations of space inversion, particle conjugation and time reversal if some very general principles of the relativistic quantum theory of these particles are valid.

One notices that the various particles belonging to a family have the same spin and the same values of the additive quantum numbers except the electric charge. The photon has a universal interaction with all charged particles; it has been found possible to connect the conservation of electric charge and this universal interaction structure, on the one hand, to the vanishing mass and unit spin of the photon, on the other. The electron and muon partake of both electromagnetic and weak interactions, but do not exhibit any strong interaction. In fact the muon family appears to be simply a duplicate of the electron family except for a change in the unit of mass. At

the present time, no basic reason has been found for this doubling, and it is perhaps the most fascinating puzzle of current elementary particle physics. The members of these two families are collectively known as leptons and they all have spin one-half. The neutral members (the electron neutrino, the muon neutrino, and their antiparticles) have extremely weak interaction with matter since they do not participate even in electromagnetic interactions.

The meson family consists of seven members which fall into a triplet of pions, a doublet of kaons and a doublet of antikaons. They are all pseudoscalar (spin zero and odd parity) and exhibit strong interactions. The charged particles are of course coupled to the photon, but even the neutral members can participate in electromagnetic interaction by virtue of the large probability for virtual dissociation into charged particles. They participate in a variety of weak interactions including the nuclear beta decay interaction.

It is found that the kaons, the hyperons (baryons other than the neutron and proton) and their antiparticles, collectively known as "strange particles," can decay by weak interactions not involving leptons or photons with a lifetime which is large compared to the natural periods appropriate to strong interactions. On the other hand, these particles are produced copiously in high-energy nuclear collisions. These two circumstances can be understood in terms of the existence of another additive quantum number, called hypercharge, which is conserved in strong and electromagnetic interactions but violated in weak interactions.

The meson-baryon system exhibits further regularities as far as strong interactions are concerned. The neutron and the proton have very nearly the same mass and similar nuclear interactions although their electromagnetic properties are quite different. The three pions have different electric charges, but again they have approximately equal masses and similar nuclear interactions. This kind of multiplet structure is evident for other strongly interacting particles: the kaons form a doublet, the sigma hyperons form a triplet, and the xi hyperons form a doublet, and the lambda hyperon remains a singlet. In view of the relative weakness of the electromagnetic interaction, it is tempting to ascribe all deviations from exact equality of the masses to the indirect action of the electromagnetic interaction. In this framework, it is possible to consider the members of a multiplet to be different states of the same particle corresponding to the values of a new quantum number. What is remarkable is that if one takes this point of view, it is possible to show that the strong interactions exhibit a remarkable invariance under a group of continuous transformations which may be viewed as the group of rotations in a fictitious three-dimensional space (or more correctly as the special unitary group SU_2 of transformations on two variables). The transformations act as follows: the singlet is unchanged, the doublet components

TABLE I. CATALOG OF ELEMENTARY PARTICLES

Particle	Family*	Spin	Mass (MeV)	Lifetime† (sec)	Antiparticle	Parity‡	Charge	Hypercharge	Baryon Number	Electron Number	Muon Number
Photon, γ	Photon	1	0	Stable	Photon, γ	-	0	0	0	0	0

* Electron and muon families are collectively known as the lepton family. The proton and neutron are both nucleons; other members of the baryon family are the hyperons.
† The neutral kaon has a long-lived component K_S^0 and a short-lived component, which are quantum mechanical superpositions of the neutral kaon and the neutral antikaon.
‡ Electron, muon, proton, neutron and lambda parities are defined by convention.

transform like the components of a spinor, and the triplet components transform like the components of a vector. This property of strong interactions is called "charge independence"; and the corresponding conserved dynamical variable (with three components) is called the isotopic spin. It then turns out that hypercharge conservation is a consequence of isotopic spin conservation and electric charge conservation. While the conservation of isotopic spin is violated by the electromagnetic (and weak) interactions, the charge independence of nuclear interactions is still expected to be satisfied to within a few per cent and experimental tests confirm this. Since the symmetry associated with invariance under isospin transformations is not directly related to space-time properties, one often refers to it as an "internal symmetry."

One might now raise the question: Which of these particles are basic constituents of matter? For the case of the atom, say the simplest of them all, the hydrogen atom, it seems easy to say that it is a composite system made up of an electron and proton bound together by an electrostatic force. However, this answer is not completely satisfactory since the electrostatic force itself is due to the exchange of light quanta, and in the process of atomic transitions photons are emitted or absorbed. Yet we do not include them as constituents of the atom. In beta radioactivity, electrons and neutrinos emerge from the nucleus, yet the nucleus is not pictured as containing either of these varieties of particles but rather as made up of protons and neutrons. The beta electron and neutrino are rather assumed to be created at the moment of emission. With the mesons taking part in strong interactions, however, such distinctions are no longer obvious, and the question of whether a particle is elementary or is composed of several other particles cannot be answered except perhaps within the context of a more quantitative but limited model. A point of view that has gained some acceptance is that *none* of these particles are elementary and that each is a composite of several particles (including perhaps itself)!

This view, while by no means inevitable or even well-established, is a possible picture, because in the realm of elementary particles we can not only add particles together to construct a composite system, we can also "subtract" particles by adding antiparticles. The claim that particles A and B go to make up the particle C is difficult to distinguish from the claim that particles \bar{B} (antiparticle to B) and C go to make up the particle A. Further, particles play a dual role. On the one hand, they are constituents of a composite system; on the other hand, they are the objects which are exchanged to generate forces between the constituents. In any case, in view of the very large number of entries in Table 1, it is not desirable to accept all of them as the ultimate constituents of matter.

This is even more forcefully brought to our attention by the recent discovery of a very large number of ultra short-lived particles. They appear as sharp resonances in multiparticle systems.

Since these "resonances" disintegrate within a short time (even on the nuclear scale!), it is difficult to view them as elementary particles, but they seem to play an important role in interaction phenomena and are produced as often as the more stable (and familiar) mesons and baryons included in Table 1. It appears at the present time that they ought to be included on more or less the same footing. A list of the better established resonances is given in Table 2 along with the mesons and baryons from Table 1. Since an unstable particle lives only for a very short time, its energy and consequently its mass cannot be sharp, and from elementary quantum mechanical considerations we would expect this "width" in the mass of a resonance to be inversely proportional to its lifetime. Since the width is what is measured experimentally, the width (rather than the lifetime) is usually quoted in connection with resonances.

Since these particles are coupled in the strong interactions, one would expect them to occur in isospin multiplets. This is in fact observed. It turns out that since strong interactions are invariant under particle conjugation and are charge independent, we could define a multiplicative quantum number called G-parity which has definite values ± 1 for mesons and meson resonances. These values are also included in Table 2.

One notes also that the meson and baryon multiplets seem to fall into further supermultiplets. Following the analogy of the isospin group, we may now ask what internal symmetry group is responsible for this interaction. We must also remember that whatever is responsible for the violation of this higher symmetry must itself be a part of the strong interaction. A scheme in which invariance under the special unitary group on three variables (SU_3) holds approximately has been successful in correlating and predicting the spectrum of particles and their interactions. The isospin group, SU_2 , is a subgroup of this unitary group. Just as for charge independence, no basic reason has been found for the origin of this "unitary symmetry." Still other symmetry groups, even wider than SU_3 and generally incorporating it, and which are even more significantly violated, are being studied. It appears that the complete understanding of these higher internal symmetries would involve not only their origin, but also the origin of their violation.

The theoretical description of the interaction of electrons and photons involves a relativistic quantum theory of the electron and photon fields (QUANTUM ELECTRODYNAMICS). While fundamental difficulties still remain, the computational techniques developed have enabled the accurate prediction of even the finer details of the electron's electromagnetic properties. Such a method of calculation completely fails for strong interactions, although there are reasons to believe that the correct theory should involve interacting quantized relativistic fields. The immediate correspondence between each kind of particle and a field as obtained in quantum electrodynamics is unlikely for the strongly interacting particles. On the other hand the answer to the question "What

TABLE 2. STRONGLY INTERACTING PARTICLES AND RESONANCES (AS OF 1964 SUMMER)

Particle or Resonance	Spin	Mass (MeV)*	Width (MeV)+	Parity	Electric Charge	Hyper- charge	Isotopic Spin	G-parity	Unitary Symmetry Assignment

* The average mass of the members of the isotopic multiplet is tabulated.
+ Since the unstable particles of Table 1 live "practically forever" on the nuclear time scale, the corresponding widths are several orders of magnitude smaller than one MeV; these are quoted here as "0".

are the primitive fields?" is not obvious. Thus we are faced with a frustrating situation: there are reasons to believe that the basic theory should involve relativistic interacting quantized fields, but there is no immediate way of deciding the number or nature of the fields or of the law of their interaction. It is to be hoped that this situation will not persist indefinitely!

Since the quantum field theory framework has not so far yielded acceptable computational techniques for strong interactions, in recent years increasing effort has gone into attempts to make a theory of the reaction amplitude ("scattering matrix elements") directly. The original hope was that the general principles of quantum theory might give sufficient information to determine the reaction amplitudes more or less completely. While this program has not so far been successful, it has given rise to a variety of computational techniques for strong interactions. These, together with the discovery of the resonances, have enabled us to understand the qualitative (and in some instances, quantitative) features of strong interactions.

To sum up, we find that we have now a very large number of "elementary" particles which, by their very number, forfeit their claim to be considered ultimate constituents of matter. We have some understanding of the regularities observed in their spectrum and their interactions, and we have discovered a variety of conservation laws. However, we still do not understand the multiplicity of these particles, nor do we have a quantitative theory of their interactions. Perhaps yet another level of discovery awaits us in our search for the constitution of matter.

ELEMENTS, CHEMICAL

The idea of simplicity underlying the bewildering complexity of nature has always been a conceptual thread underlying man's view of the

world. The Greek philosophers of antiquity were among the first to record their speculations, and we are to this day influenced in an unconscious way by their thoughts on the elements, which they supposed to be the ultimate components of matter and chemical change. Thus we speak of "man's battle with the elements" and "the raging elements" in unconscious reflection of the ideas of Thales, Anaximenes, Heraclitus and Empedocles of the fifth century B.C. who believed that all matter was made of one or more of the elements earth, air, fire and water. These ideas did not prove particularly fruitful in advancing our understanding of the nature of matter and chemical change. Nevertheless, it was not until van Helmont (1648) that they were challenged on a rational basis.

In 1662, Robert Boyle, in the "Sceptical Chymist" gave a reasonably clear definition of a chemical element with operational overtones which we can accept today. "I mean by elements, . . . certain Primitive and Simple, or perfectly unmingled bodies; which not being made of any other bodies, or mingled bodies, are the Ingredients of which all those called perfectly mixt bodies are immediately compounded, and into which they are ultimately resolved." He gave no list of elements, however, this being left to Lavoisier who published a naturally incomplete, but remarkably accurate list in 1789, in his justly famous "Traité de Chimie."

The Definition of "Element." In modern language, Boyle can be paraphrased in the following way: an *element* is a chemical species that cannot, by ordinary chemical manipulation be decomposed into a number of simpler chemical species. It is the entity that survives intact the infinite variety of transformations that a sample of matter can be caused to undergo. Every *compound* is composed of two or more of these species and can be decomposed into them by suitable chemical procedures. This definition provides an operational means of identifying an element in terms of laboratory procedure, and by it, any species that defies decompositional efforts must be classified as an element. Such an assignment must of course be somewhat tentative, since in a number of cases, substances that have stubbornly resisted decomposition and therefore carried the classification, have ultimately yielded as new techniques developed.

With the recent growth in detailed knowledge of atomic structure, it became possible to define an element in terms of the submicroscopic structure of matter. Such a definition is relieved of the ambiguities mentioned above. Thus an element is a sample of matter that consists of only one kind of atom, the atoms being identified in terms of their atomic number, or nuclear charge. Each element is composed of atoms having characteristic nuclear charge and an equivalent number of electrons. This nuclear charge can be determined by the charged-particle scattering technique first employed by Rutherford or by the simpler and more precise method of Moseley which relates the frequency of the characteristic x-rays produced

by the element upon electron bombardment to the nuclear charge z by means of the equation

$$w = R(z - b)^2$$

where w is the wave number of the x-ray, z is the nuclear charge, and b and R are constants.

This definition removes the ambiguities created by such observations as the decomposition of elemental molecular hydrogen or nitrogen by high temperatures into atomic species, or the decomposition of the rare gases into charged species in an electric discharge. This type of decomposition, which does not effect the underlying nuclear structure is thus excluded from the operational definition originating with Boyle.

Numbers and Kinds of Elements. The number of substances recognized as chemical elements has steadily increased since the publication of Lavoisier's list which included about thirty of the true elements. Today it is recognized that there are some 90 naturally occurring elements, the exact number depending upon the level of abundance considered limiting. There are also about 13 artificial ones with this latter number possibly increasing as the techniques of nuclear science improve. The artificial elements include those with atomic numbers above 92 as well as promethium and technetium. Technetium is also observed in stars, and in that sense is naturally occurring.

The 103 presently known elements represent distinct chemical species differing by integral units of positive charge (corresponding to the charge of the proton) beginning with element number 1, hydrogen, and progressing through element number 103. Species having nuclear charges between 1 and 103 have all been identified, so it can be said that the list of elements is complete, except for the possibility of adding new ones with atomic numbers greater than 103. The list of elements, however, is not expected to get much longer since the instability of the nucleus rapidly increases with high atomic number, all of the elements beyond bismuth (83) being naturally radioactive.

Most of the elements exhibit variations in mass, due to the varying numbers of neutrons present in their nuclei. Atoms having the same nuclear charge but differing in mass number or atomic weight are referred to as ISOTOPES. If all of these are considered, then there are approximately 1000 different atomic species represented in the list of chemical elements. Only 18 of the elements existing in nature exhibit a single mass number, and some, tin being a good example, have as many as ten naturally occurring stable species differing only in their neutron number or mass. All of the elements exhibit a variety of mass modifications which are artificially produced, but these are unstable or radioactive. These artificially produced species, of course, make up the bulk of the previously mentioned 1000 different entities. The *naturally occurring* radioactive isotopes, in addition to those beyond bismuth, include carbon 14, chlorine 36, vanadium 50, potassium 40, rubidium 87, indium 115, lanthanum 138, neodymium 144, samarium 147, lutetium 176, tantalum 180, rhenium 187, and platinum 190.

The Natural Distribution of Elements. The relative abundance of the elements is quite different for the earth's crust from what it is thought to be for the universe as a whole. These terrestrial abundances are listed in Table 1 from which it can be seen that only thirteen elements comprise over 98 per cent of the earth's crust, the oceans, and the atmosphere.

TABLE 1. THE THIRTEEN MOST ABUNDANT ELEMENTS IN THE EARTH'S CRUST

Element	Abundance (%)
Oxygen	49.52
Silicon	25.75
Aluminum	7.51
Iron	4.70
Calcium	3.39
Sodium	2.64
Potassium	2.40
Magnesium	1.94
Chlorine	1.88
Hydrogen	0.88
Titanium	0.58
Phosphorus	0.120
Carbon	0.087

It will be noted that many of the common and important elements of commerce are not included in this list, but rather belong to the remaining 2 per cent of the earth's crust. Copper, lead, and nitrogen are especially conspicuous by their absence.

If we turn our attention now to cosmic abundances, the list has quite a different make up (see Table 2). This list of course is known with considerably less accuracy since it is our attempt to guess at the relative abundance of the chemical elements in the entire universe: our galaxy, all the other galaxies, and the vast, but not entirely empty spaces in between. This information has largely been gathered by spectroscopic studies of the light emitted by the luminous bodies in these galaxies and by careful analysis of the samples of off-planet material (meteorites) that constantly shower the earth.

TABLE 2. THE THIRTEEN MOST ABUNDANT ELEMENTS IN THE UNIVERSE

Element	Relative Abundance*
Hydrogen	3.5×10^8
Helium	3.5×10^7
Oxygen	2.2×10^8
Nitrogen	1.6×10^8
Carbon	8×10^4
Neon	2.4×10^4
Iron	1.8×10^4
Silicon	1×10^4
Magnesium	9×10^3
Sulfur	3.5×10^3
Nickel	1.3×10^3
Aluminum	8.8×10^2
Calcium	6.7×10^2

* These abundances are relative to silicon taken as 1×10^4 .

It can readily be seen that this list is quite different from the terrestrial abundance list. For the universe as a whole, the elements hydrogen and helium far outrank all others, while on the earth, hydrogen is only tenth in abundance and helium doesn't even appear on the list. Oxygen remains high, and nitrogen, absent from the terrestrial list, is the fourth most abundant element when cosmic abundances are considered. In Fig. 1, some of the interesting variations in abundance are displayed. The relative abundance is plotted against mass number.

It will be noted that elements with atomic weights that are multiples of four and two are more abundant than nearby elements with relatively similar atomic weights. Examination shows that those elements having *proton or neutron* numbers 8, 50, 82, and 126 also exhibit maxima. These numbers are so-called magic numbers conferring an especially high degree of nuclear stability.

The Origins of the Elements. Considerable speculation has been devoted to the question

of the origin of the particular atomic weight distribution of elements thought to represent cosmic abundances. Examination of Fig. 1 suggests that this distribution is related to nuclear stability so that it would seem fruitful to consider what kind of an environment and sequence of events might lead to the observed distribution.

It should first of all be clear that in none of these theories is an attempt being made to truly consider *origins*, but only to explain the present distribution of atomic weights relative to some rather arbitrarily chosen point of time in the past. Nothing is postulated concerning the events preceding the zero time chosen.

One of the earliest and most popular theories, due mainly to Gamow, assumes that at time zero, the universe consisted of a dense mass of neutrons and radiation which at that time began a rapid expansion. During the early period, the temperature and density rapidly fell to values prevalent today. In the first five minutes, the universe was converted to a mixture of protons, neutrons, and

FIG. 1. [From Cameron, A. G. W., *Sky and Telescope*, 254 (May, 1963)]

electrons; in the next five minutes, sufficient cooling had occurred to permit thermonuclear reactions to occur, leading predominantly to the light elements. By the end of thirty minutes, the temperature of the expanding universe had dropped below that required for thermonuclear reactions in light elements and the distribution that we observe today, in which about 99 per cent of the universe is composed of hydrogen and helium, was achieved. The build-up of the heavier elements is somewhat less clear. This theory assumes that the buildup was generally by neutron capture, but the absence of any stable nucleus of mass 5 throws some doubt on this general mechanism.

A theory based on equilibrium arguments involving the relation of binding energies of the nuclei to their abundance, predicts a much higher initial density of matter than the preceding kinetic theory and suggests that all of the elements were formed in exploding novae. While this theory is adequate in predicting abundances up to about mass 60, it seems quite inadequate for the heavier elements.

The most recent theory of formation of the elements, which is also the most detailed, assumes a steady-state process, without beginning or end. Matter is continuously formed and condenses into new stars and galaxies which undergo a series of evolutionary changes as a result of internal nuclear reactions and eventually again distribute their matter into interstellar space.

The observational and experimental basis for this theory is mainly the *variations* in elemental distribution that are known for various types of stars in our galaxy. These variations suggest that the heavier elements, especially, are the natural consequence of stellar evolution. Detailed reaction schemes have been developed which account quite well for the high abundance of hydrogen and helium, and the low abundance of carbon, nitrogen and oxygen. The peak in mass number around 56 is also quite adequately explained. These reaction schemes suggest an age for our galaxy between 10 and 15 billion years.

ENERGY. See WORK, POWER AND ENERGY.

ENERGY LEVELS

The term "energy level" is used in referring to discrete amounts of energy which atoms and molecules can have with respect to their electron or nuclear structure. The concept of permissible discrete energy levels was first introduced by Planck in explaining the physical basis for the spectral distribution of blackbody radiation. A second related principle due to Planck was that the emission and absorption of radiation are associated with transitions between these energy levels, the energy thereby lost or gained being equal to the energy, $h\nu$, of the quantum of radiation. Here h is Planck's constant and ν is the frequency of the radiation.

The first application of energy levels in the electron structure of atoms to explain optical spectra was made by Bohr. The original Bohr atom had as its basis that the only allowable states of an atom were those in which the electronic angular momentum was an integral multiple of $h/2\pi$. Circular orbits suggested by Bohr were extended by Sommerfeld to include the quantization of momentum in elliptic orbits, and to provide an improved explanation of optical spectra.

These early concepts were modified by the development of the theory of wave mechanics, in which it was shown that the allowable "stationary" states for the electrons in an atom must represent solutions of the Schrodinger wave equation. These solutions are conveniently represented by a set of "quantum numbers" for each electron. On this basis the electron structure of an atom containing any number of electrons can be built up. Two further concepts which are essential to this picture, however, are electron spin proposed by Uhlenbeck and Goudsmit, and the exclusion principle due to Pauli. In addition to the angular momentum of the electron in its orbit, each electron possesses angular momentum due to spin about an axis. The Pauli exclusion principle specifies that no two electrons in an atom can exist in the same quantum state, corresponding to the same set of quantum numbers.

Each electron in an atom can be characterized by four quantum numbers, n , l , m_l , m_s . The energy of an electron depends principally upon the positive integer n , and larger values of n correspond to larger electronic orbits. The quantum number l possesses physical significance in terms of angular momentum in the orbit, and is constrained to have the values of zero or positive integers less than n . The number, m_l , represents the component of l along a given axis, and must take on the values of zero or positive and negative integers whose absolute values are less than or equal to the value of l . The quantum number,

m_s , can be $+\frac{1}{2}$ or $-\frac{1}{2}$, and represents the component of the spin along the axis.

Within a given atom, electrons having the same value of the principal quantum number, n , form a definite group or "shell." Those electrons possessing the same value of l for a given value of n are in the same subgroup or "subshell." The possible number of electrons in a shell or subshell depends upon the possible values of m_l and m_s . Whenever a subshell is filled, the total angular momentum of the electrons involved is zero. Electrons outside of filled subshells contribute additional angular momentum which is summed vectorially and assigned the numbers J , L and S . Here J is representative of the total angular momentum, L the orbital angular momentum, and S the spin angular momentum.

An atom is stable only when it exists in the state for which the quantum numbers of its electrons give the lowest total energy. The energy of the atom may be increased to a higher level by having an electron "excited" to another state

represented by a different set of allowed quantum numbers. Transitions back again to the "ground" state will be accompanied by the emission of radiation. Wave mechanics indicates, however, that only certain transitions from one quantum state to another can be probable. These "selection rules" specify that $\Delta L = \pm 1$ and that $\Delta J = 0$ or ± 1 .

Following the principles just given, an electron energy-level diagram can be constructed for the excited states of the atoms of any particular isotope. Discrete energy levels will exist for the allowed quantum states of excited electrons. The spectrum of radiation which can be emitted from the isotope will be determined by the energy differences between these states, where the transitions involved are allowed by selection rules. Figure 1 illustrates such an energy-level diagram for sodium.

This diagram indicates that very little difference in energy level results from changes in the electron spin orientation. These orientations cor-

FIG. 1. Energy-level diagram for sodium. The large numbers are wave lengths in \AA of radiation emitted or absorbed during the indicated transitions. Principal quantum numbers are shown as integers.

respond to different values of J for the same value of L . No attempt is made to show a separation in the diagram for the cases of $L = 2$ and $L = 3$. Such closely spaced energy levels due to the effect of the coupling of the electron spin give rise to "fine structure" in spectra.

Many spectral lines, when examined with high resolving power instruments, are found to exhibit a still finer structure of several lines very close together. This is termed "hyperfine structure" and has been found to be due to two causes. One is the isotope effect in which atoms of different isotopes of the same element possess slightly different excited electron energy levels. The other cause of hyperfine structure has been determined to be due to the fact that the atomic nucleus also possesses angular momentum, which is vectorially added to the electronic angular momentum and quantized. Differences in the resultant states of the atom correspond to very small differences in the energy levels and hence in the observed spectrum.

Another source of structure in spectra results when the atoms emitting or absorbing the radiation are in a magnetic or an electric field. In a field, space quantization in the direction of the field takes place. The values of the magnetic moment or electric moment of the atom associated with the various possible components of angular momentum as quantized in the field direction result in different energy levels. This splitting of levels is referred to as the Zeeman effect in the case of an applied magnetic field, and the Stark effect in the case of an applied electric field (see ZEEMAN and STARK EFFECT). The amount of splitting increases with the intensity of the superposed field. In addition, the spectral structure can vary due to a tendency for the orbital momentum, L , and the spin momentum, S , to become uncoupled and undergo space quantization independently in high fields. In weak fields, the space quantization is determined from the total angular momentum J .

Any electron of an atom may be excited to some higher allowed energy level by absorption of the amount of energy specified by the difference in the energy levels involved. By absorption of a sufficient amount of energy, any electron can be removed from an atom, resulting in ionization. It is not necessary to consider only the outermost loosely bound electrons. When electrons from inner shells are excited or removed, the process of returning to the "ground" or lowest energy state involves the emission of "characteristic" x-rays. They are "characteristic" in that the x-ray spectrum produced is typical of the particular atom producing the radiation. Atoms of higher atomic number and transitions involving electrons in innermost shells produce higher-energy radiation. Absorption, as well as emission, of characteristic x-ray radiation is observed between allowed electronic energy levels. For further information on atomic spectra and energy levels, see reference 1.

In addition to the energy levels associated with particular types of atoms, wave mechanics

shows that discrete quantum states and energy levels are associated with molecular structure. New energy levels arise from vibration and rotation of molecules. To illustrate the allowable vibrational states for a diatomic molecule, consider Fig. 2, which shows the mutual force, F , and the potential energy, V , plotted as a function of the separation, r , between the two atoms. Possible energy levels are indicated by the dotted lines. Even the lowest state corresponds to an energy greater than V_0 , where the force between the atoms would be zero, and hence has some associated kinetic energy.

FIG. 2. Mutual potential energy V and force F as a function of atomic separation in a diatomic molecule. F is repulsive when positive and attractive when negative.

The rotation of a molecule has a quantized angular momentum which can be vectorially combined with that of the electrons. Transitions from one level to another usually involve a change in the electronic state as well as in the rotational state. Since energy differences due to allowed changes in rotational motion are very small compared to the energy differences in electronic states or vibrational states, the effect of transitions in rotational states is to produce bands of very closely spaced frequencies in the emission and absorption spectra. Such "rotational" bands are observed in molecular spectroscopy, depending upon what other transitions may be simultaneously involved, in the ultraviolet region, the visible, the infrared, and even the microwave region. See reference 2 for further details on molecular energy levels and associated spectra.

An atom may not only combine with others to form a molecule, but may be one of a large number of atoms forming a crystal. Here solutions to the wave equation show that within the solid, the individual energy levels of the free atom broaden into bands of overlapping levels. This is illustrated in Fig. 3. The bulk electrical and optical properties of solids are determined

FIG. 3. The electron levels of a free atom split into bands when the atom enters a solid.

by the nature of these energy-level bands. Metals have the highest occupied energy band unfilled, while satisfying the exclusion principle that no two electrons occupy the same state. This permits electrons to gain energy under the application of an electric field and flow freely through the solid. Insulating crystals have the highest occupied energy band filled and appreciably separated from the next higher band. Semiconductors represent an intermediate situation where electrons can be injected into an unfilled band to contribute to conduction.

If the solid crystal is not completely regular but contains imperfections or impurity atoms, specific electron energy levels will be associated with these sites. This condition is responsible for luminescence and phosphorescence in certain solids. Additional information on energy levels and energy bands in solids is given in reference 3.

Finally, it should be mentioned in addition to energy levels associated with the electronic structure of atoms and the motion of atoms in molecules, there are energy levels associated with the structure of nuclei. Such levels evidence themselves in various ways, particularly through the different energies of the electromagnetic radiation, or gamma rays, emitted from excited nuclei.

ENTROPY

The word "entropy" was coined from the Greek by Rudolph Clausius in 1850 to mean "transformation". He applied it to a thermodynamic function, S , defined by the differential equation

$$dS = dQ/T \quad (\text{reversible}) \quad (1)$$

where dQ is the element of heat added reversibly to a system at absolute temperature T . In the classical macroscopic approach to thermodynamics, no meaning is assignable to entropy. The classical view is that thermodynamics is a machine into which some facts are put and other facts emerge.

In 1948, Claude Shannon³ demonstrated that the change in the function defined by

$$S_1 = k \sum p_i \log p_i \quad (2)$$

measures the amount of information in any message (p_i = probability that the receiver assigns to the receipt of the i th possible). The sum is over all possible messages. It has been shown that the entropy of Clausius is derivable from that of Shannon.¹ Before considering this derivation, a simple example of the meaning of entropy will be considered. Suppose you are asked to guess which number from 1 to 100 has been secretly written on a piece of paper. Taking each p_i equal to $1/100$, it is found that in the above equation, $S_1 = k \log (100)$. Letting k equal 1 and taking the logarithm to the base 2 gives $S = 6.67$ "bits." This means if each question has only two possible answers (i.e., "yes" or "no"), it will take between 6 and 7 questions to find the number. The questioner begins by asking, "Is the number between 1 and 50?" Depending on the answer, he continues by reducing the possible numbers by a factor of 2 with each question. Since $2^6 = 64$ and $2^7 = 128$, the questioner will surely find the number in 7 questions and 1/3 of the time he will find it in 6 questions. Entropy may therefore be said to measure the state of ignorance of a person relative to a well-defined question, if the person only knows a probability distribution. It measures the expected number of questions he will have to ask in order to go from his state of partial knowledge to a state in which he knows everything about the well-defined question. According to the Shannon derivation,³ S_1 represents the amount of information in a message telling the actual number written on the paper (for someone for whom $p_i = 1/100$). This interpretation of entropy is used in information theory in the design of codes and in the analysis of information transmission systems.

To make the connection with classical thermodynamics, consider a physical system and ask the question "In what quantum state is this system?" Of course one can never say in which quantum state a system resides but rather can only give a

probability for the system being in a particular state. The probability distribution for the states must be consistent with the observer's knowledge. The information theory principle of maximum entropy says to choose a set of probabilities which agrees with the available data and maximizes the entropy, for, in accordance with the meaning of entropy, this is the most noncommittal view. A state of equilibrium is, by the definition given by Gibbs,⁴ a state of maximum entropy. From the information theory point of view, it is a state in which all of the random motions which can take place are, in fact, taking place so that the observer knows as little about the systems as it is possible to know beyond his knowledge of the "constants of the motion." If we describe a system by giving only the pressure, temperature and volume (or other gross properties), we omit many details. Entropy measures how much more there is to be said before the quantum state is specified.

As an illustration, consider a closed system of particles. From quantum mechanics, we know the system is in some state, i , with energy ϵ_i . If we make an observation of ϵ , the best we can do is infer that it represents the expectation energy, $\langle \epsilon \rangle$, for this is a repeatable quantity associated with the motion. To generate the appropriate probability distribution, we maximize S_i defined in Eq. (2), with the following constraints on the p_i :

$$\sum p_i = 1 \text{ (the system is in some state)} \quad (3)$$

$$\sum p_i \epsilon_i = \langle \epsilon \rangle \text{ (the system has an expectation energy)} \quad (4)$$

Maximization of the entropy subject to the two equations given leads to the probability distribution

$$p_i = e^{-\psi - \beta \epsilon_i} \quad (5)$$

The resultant entropy, $S_{i,\max}$, is, by Gibbs' definition, the equilibrium entropy. The probability distribution is known as the Boltzmann distribution. It is easy to demonstrate that the parameter β is equal to $1/kT$ where k is the Boltzmann constant and T is the absolute temperature. If the observer is limited to macroscopic observations concerned with the energy of a body, the above derivation leads to laws which connect the observations to one another. That is, the quantities ψ , β , $\langle \epsilon \rangle$, S and various combinations are related to one another by equations from which p_i and ϵ_i have been eliminated. These relations are known as the "Laws of Classical Thermodynamics".

For example, since, from Eq. (4)

$$d\langle \epsilon \rangle = \sum_i \epsilon_i dp_i + \sum_i p_i d\epsilon_i$$

it is clear that the changes in the energy of a body may be divided into two classes: (a) those of the type $\sum_i \epsilon_i dp_i$ which necessarily change the probabilities and therefore the entropy (non-isentropic) and (b) those in which $\sum_i \epsilon_i dp_i = 0$ (i.e., isentropic). This division into two classes of energy exchange gives rise to the concepts of "heat" and "work." For a detailed account of the derivation see reference 2.

Entropy, as a logical device for generating probability distributions, has been applied in reliability engineering, decision theory, and the theory of steady-state irreversible processes. (See list of references with reference 5.) The generalized approach to entropy usage was initiated by Jaynes.⁶

EQUILIBRIUM

In the elementary sense of the macroscopic (visible to the naked eye) system, equilibrium is obtained if the system does not tend to undergo any further change of its own accord. Any further change must be produced by external means.

Mechanical and Electromagnetic Systems. Equilibrium in mechanical and/or electromagnetic systems is reached when the vectorial summation of generalized forces applied to the system is equal to zero. In any potential field, that is, gravitational or electric vector potential, force can be expressed as gradient of potential (magnetic force however, is a curl of a vector potential). The potential energy therefore has an extremum at the equilibrium configuration. For example, a system such as a mass suspended by a string against the gravitational force (or its weight) is at mechanical equilibrium if the tensile force in the string is equal to the weight of the mass it supports. The d'Alembert principle further states that the condition for equilibrium of a system is that the virtual work of the applied forces vanishes.

Thermodynamic Systems. When a hot body and a cold body are brought into physical contact, they tend to achieve the same warmth after a long time. These two bodies are then said to be at thermal equilibrium with each other. The zeroth law of thermodynamics (R. H. Fowler) states that two bodies individually at equilibrium with a third are at equilibrium with each other. This led to the comparison of the states of thermal equilibrium of two bodies in terms of a third body called

a thermometer. The temperature scale is a measure of state of thermal equilibrium, and two systems at thermal equilibrium must have the same temperature (see THERMODYNAMICS).

Generalization of equilibrium consideration by the second law of thermodynamics specifies that the state of thermodynamic equilibrium of a system is characterized by the attainment of the maximum of its ENTROPY. Thermodynamic coordinates are defined in terms of equilibrium states.

Equilibrium between two phases of a system is reached when there is no net transfer of mass or energy between the phases. Phase equilibrium is determined by the equality of the Gibbs functions (also called free enthalpy, free energy, or chemical potential) of the phases in addition to equality of their temperatures and stresses (such as pressure and/or field intensities—intensive properties). Equilibrium of first-order phase change requires continuity of slope or first derivative of the Gibbs function with respect to an intensive property and is generalized as the Clapeyron relation. Second- and higher-order phase changes are given by the condition of continuity of curvature or second derivative of the Gibbs function and so on.

Chemical or nuclear equilibrium of a reactive system is reached when there is no net transfer of mass and/or energy between the components of a system. At chemical or nuclear equilibrium, the Gibbs function of the reactants and the products must be equal according to stoichiometric proportions, in addition to uniformity in temperature and stresses. Chemical equilibrium is summarized in the form of the Law of Mass Action. The trend for the displacement from an equilibrium state is specified by LeChâtelier's principle.

Thermodynamic equilibrium is reached when the condition of mechanical, electromagnetic, thermal, phase, and chemical and nuclear equilibrium is reached.

Stability of Equilibrium. A process or change of state carried out on a system such that it is always near a state of equilibrium is called a quasi-stationary equilibrium. This requires that the process be carried out slowly. If a mechanical system is initially at the equilibrium position with zero initial velocity, then the system will continue at equilibrium indefinitely. An equilibrium position is said to be stable if a small disturbance of the system from equilibrium results only in small, bounded motion about the rest position. The equilibrium is unstable if an infinitesimal displacement produces unbounded motion. In the gravitational field, a marble at rest in the bottom of a bowl is in stable equilibrium, but an egg standing on its end is in unstable equilibrium. When motion can occur about an equilibrium position without disturbing the equilibrium, the system is in neutral (or labile, or indifferent) equilibrium, an example being a marble resting on a perfectly flat plane normal to the direction of gravity. It is readily seen that stable equilibrium is the case when the extremum of potential is a minimum.

When dealing with general thermodynamic systems, the fact that entropy tends to a maximum in the trend toward equilibrium of a natural process generalizes the above mechanical consideration with respect to stability. An equilibrium state can be characterized as a stable equilibrium when the entropy is a maximum; neutral equilibrium when displacement from one equilibrium state to another does not involve changing entropy; and unstable equilibrium when entropy is a minimum. Any slight disturbance from an unstable equilibrium state of a system will lead to transition to another state of equilibrium.

Statistical Equilibrium. In the microscopic sense, that is, treating systems in terms of elemental particles such as molecules, atoms, and other material or quasi-particles (such as photons in radiation, phonons in solids and liquids, rotors in liquids), equilibrium states are recognized as the most probable states. An equilibrium state of a system is therefore defined in terms of most probable distributions of its elements among microscopic states which may be defined in terms of energy states. In this sense, statistical equilibrium is a condition for macroscopic equilibrium and an equilibrium state of a system is one of its extremal states. In the methods of STATISTICAL MECHANICS, the probability of distribution is expressed in terms of the density of distributions in the phase space. Based on the Liouville theorem, if a system is in statistical equilibrium, the number of the elements in a given state must be constant in time; which is to say that the density of distribution at a given location in phase space does not change with time. For an isolated system, the distribution is represented by a microcanonical ensemble. At equilibrium, no phase point can cross over a surface of constant energy, and the density of distribution is preserved. In this case individual molecules of a system can be represented by phase points. Any part of an isolated system in statistical equilibrium can be represented by a canonical ensemble. A subsystem of a large system in thermal equilibrium also behaves like the average system of a canonical ensemble. A system and a constant temperature bath together can be considered as an isolated system. A phase point in a canonical ensemble can represent a large number of molecules, thus accounting for strong interactions. A canonical ensemble is characterized by its temperature and is therefore pertinent to the concept of thermal equilibrium. When applied to equilibrium of systems involving mass exchange, such as a chemical system, we have a "particle bath" in addition to a constant temperature bath. The pertinent representation for equilibrium including mass exchange as well as energy exchange is known as a grand canonical ensemble, which accounts for the chemical potentials of its elements.

When applied to a system with a large number of elements, the distributions are measured by thermodynamic probability (W); the most probable distribution is such that W is a maximum. This optimal principle is consistent with the condition of maximum entropy (S) given in

the above. The Boltzmann hypothesis states that $S = k \ln W$, where k is the Boltzmann constant.

Depending on the specifications of W , namely, those of Maxwell-Boltzmann (for low concentration of distinguishable particles, weak interaction and high temperature, such as a dilute perfect gas), Fermi-Dirac (for elemental particles with antisymmetric wave functions at high concentrations of indistinguishable particles and low temperatures, such as electrons in metal), or Einstein-Bose (for elemental particles with symmetric wave functions, such as He^4 at high concentration of indistinguishable particles and low temperature), equilibrium distributions take different forms (see BOSE-EINSTEIN STATISTICS and FERMI-DIRAC STATISTICS). The Maxwellian speed distribution in a dilute perfect gas is a distribution based on Maxwell-Boltzmann statistics.

As a consequence of molecular considerations, when two systems are connected for transfer of mass without significant transfer of energy, such as two containers at different temperatures connected by a capillary tube, we have the relation of thermal transpiration.

Trend toward Equilibrium. The mechanism by which equilibrium is attained can only be visualized in terms of microscopic theories. In the kinetic sense, equilibrium is reached in a gas when collisions among molecules redistribute the velocities (or kinetic energies) of each molecule until a Maxwellian distribution is reached for the whole bulk. In the case of the trend toward equilibrium for two solid bodies brought into physical contact, we visualize the transfer of energy by means of free electrons and phonons (lattice vibrations).

The Boltzmann H -theorem generalizes the condition that with a state of a system represented by its distribution function f , a quantity H , defined as the statistical average of $\ln f$, approaches a minimum when equilibrium is reached. This conforms with the Boltzmann hypothesis of distribution in the above in that $S = -kH$ accounts for equilibrium as a consequence of collisions which change the distribution toward that of equilibrium conditions.

Consideration of perturbation from an equilibrium state leads to methods for dealing with rate processes and methods of irreversible thermodynamics in general.

Fluctuation from Equilibrium. A necessary consequence of the random nature of elemental particles in a body is that the property of such a body is not at every instant equal to its average value but fluctuates about this average. A precise meaning of equilibrium can only be attained from consideration of the nature of such fluctuations. In the above, we have repeatedly considered a "large" number of particles. It is important to know how large a number is "large." When considering fluctuation of energy from an average value in an isolated system, the ratio of the two is given to be proportional to $1/\sqrt{N}$, where N is the total number of elements in the system. This is also the magnitude of the fluctuation of number of particles in a system involving trans-

formation of phases and chemical and nuclear species. An equilibrium state is one at which the longtime mean magnitude of fluctuation from the average state is independent of time and this magnitude has reached a minimum value.

Large perturbation from a given state of fluctuation leads to a relaxation process toward a state of equilibrium. The relaxation time, for instance, measures the deviation from quasi-stationary equilibrium of a process which is carried out at a finite rate.

EXCITONS

Excitons are neutral, nonmagnetic, and mobile modes of electronic excitation in insulating crystals and may be regarded as quanta of the classical polarization field in a dielectric medium. They are fundamental in the description of the interaction of light with nonmetals and play an important role in energy transport.

The original model of an exciton, developed by Frenkel in 1931, is based on the tight-binding description of a solid. In this description, applicable primarily to molecular crystals, excitons are to be identified with excited states of the constituent molecules; because of the Coulomb interaction between electrons on adjacent molecules, such excited states cannot remain localized but spread through the solid as a "wave of excitation." Frenkel's model does not take into account the possibility that an excited electron may transfer to a nearby lattice site, in effect leaving behind it a positive hole. So long as the attraction between electron and hole keeps the two from drifting apart, the resulting entity will still be a neutral form of electronic excitation, i.e., an exciton. Thus a more general picture of an exciton is that of a bound electron-hole pair; the tight-binding exciton simply has the two bound at a single site so that the separate identities of electron and hole are lost. It is not, however, strictly accurate to describe the tightly bound exciton in terms of a *single* electron-hole pair, as many electrons may participate in a given excited state. The single-pair picture works well in materials with large dielectric constant and/or small reduced electron-hole mass, particularly in semiconductors. In such solids, the electron-hole separation may attain the size of many lattice cells, and it becomes appropriate to describe the exciton as a positonium-like "atom" imbedded in a smooth dielectric medium (Wannier-Mott model). This weak-binding model is improved by

taking into account the band structure of the solid: an electron from a conduction band, characterized by parameters describing this band (symmetry, effective mass, etc.), is bound to a hole from a valence band, with the resulting exciton energy lying within the band-gap. Typically, the exciton levels are within tenths of an electron volt below the conduction band edge, out of total gap energies of several electron volts. When the electron-hole separation is of the order of a few lattice spacings, as is the case in alkali halides and solid rare gases, neither description of the exciton is quantitatively accurate, and more elaborate but less successful schemes have been devised (electron transfer model, excitation model). The great variety of properties of excitons of the various types is best illustrated by the enormous range of effective masses: these vary from as much as hundreds of electron masses for tightly bound triplet excitons (excitons in which electron and hole have parallel spin; the necessary spin flip impedes the propagation of triplet excitons) down to tenths and even hundredths of an electron mass for sums of conduction and valence band masses in some weakly bound cases.

Extensive experimental studies of excitons in molecular crystals, primarily in crystals of aromatic hydrocarbons, have been carried out as an aid in understanding the electronic structure of these materials. Of considerable importance in these studies is the existence of Davydov splitting of spectral lines: a given excited state of a molecule gives rise to as many different excitons (differing in energy, coupling to light, polarization) as there are translationally inequivalent sites in a unit lattice cell. Energy transport via excitons is investigated in these materials by observing optical spectra when foreign ("guest") molecules are imbedded dilutely in the "host" crystal; perturbation of the host material can be minimized if the impurity differs from the host only in isotopic content. It is also possible to observe collisions between excitons in pure materials; blue fluorescence has been seen emitted as the result of the annihilation of two colliding triplet excitons initially produced by red light.

The most striking evidence for the weakly bound model of an exciton is observed in hydrogen-like series of absorption lines—notably in Cu_2O , also in CdS and PbI_2 —which the simplest form of this model predicts. The model can be further probed by subjecting the excitons to electric and magnetic fields, also to strain fields. Such studies have yielded detailed understanding of much of the band structure of Cu_2O and CdS , materials in which this structure was not so accessible otherwise.

Absorption of light in insulating materials (in pure crystals, also emission) is directly related to the production (in pure crystals, also decay) of excitons. Only excitons with very small wave vectors couple to visible light since the latter has wavelengths of hundreds of lattice constants; yet the exciton wave vector is not so small as to escape detection, and the mobile character of optically produced excitons has been verified via the Lorentz

force acting on a moving exciton in a magnetic field. Another selection rule important in exciton-photon coupling comes about from the fact that the matrix element for the production of an exciton contains in lowest order a vector quantity, the transition moment μ . Only excitons with wave vector perpendicular to μ couple to light. The interaction with photons results in mixed exciton-photon modes, often called polaritons. The finite mass of the exciton part of a polariton gives rise to effects associated with spatial dispersion, e.g., anomalous modes of light propagation. Excitons, though intrinsically non-current-carrying entities, are also instrumental in photoconductivity and photoemission; the necessary charge carriers are produced from ionization of impurity states by excitons or from ionization of the excitons themselves.

To obtain bonafide absorption of light, an energy sink is needed for the excitons; except for possible re-emission at lower frequencies, phonons provide the main sink of energy. The exciton-phonon interaction may bring about the formation of "trapped excitons," which carry along a region of self-produced lattice distortion. Phonons have important effects on the line shapes of optical exciton spectra, particularly in the alkali halides where absorption peaks may attain widths of tenths of an electron volt even at low temperatures. Phonons make possible the optical production of "indirect" excitons, excitons which have wave vectors large compared to those of light. One, as yet little understood, phonon effect is the empirical Urbach law, observed in many substances, notably in the alkali halides. According to this law, absorption below the absorption edge decreases exponentially with energy, the exponent varying inversely with the temperature.

Excitons have also been studied in the x-ray region. Other related topics include vibrational excitons, propagating vibrational states in molecular crystals which are not strictly electronic in nature yet share the properties of Frenkel excitons. Excitons are also of interest in long-chain organic molecules which act like one-dimensional crystals; thus they even have biological significance.

EXCLUSION PRINCIPLE. See PERIODIC LAW AND PERIODIC TABLE.

EXPANSION, THERMAL

Definition and General Remarks. All substances change their shapes as a consequence of undergoing changes in temperature. A measure of this change is the thermal coefficient of expansion. For solids in the form of a thin rod or cable, this change is confined (to first order) to a change in length, and a linear coefficient of expansion is thus defined by

$$\alpha_0 = \frac{1}{L_0} \left(\frac{\partial L}{\partial t} \right)_P \quad (1)$$

where L_0 is the length of the specimen at 0°C and the subscript P implies that the pressure is kept constant. Correspondingly, for fluids and for solids of arbitrary shape, one defines a cubical or volume coefficient of expansion, β_0 , by the relation

$$\beta_0 = \frac{1}{V_0} \left(\frac{\partial V}{\partial t} \right)_P \quad (2)$$

with V_0 being the volume at the reference temperature (usually chosen to be 0°C). It may readily be shown that $\beta_0 = 3\alpha_0$. Thus for solids one usually tabulates values of α_0 while, of course, only β has meaning for fluids. Whereas β_0 is simply $1/273$ for all ideal gases (this follows from the equation $PV = nRT$), there exists a wide variation for β values among liquids. Table 1

TABLE 1. LINEAR COEFFICIENTS OF EXPANSION, α , FOR SOME SOLIDS AND CUBICAL COEFFICIENTS OF EXPANSION, β , FOR SOME LIQUIDS AT ROOM TEMPERATURE

	α (/°C)	β (/°C)
Aluminum	25.0×10^{-6}	
Copper	16.8×10^{-6}	
Nickel	12.8×10^{-6}	
Sodium	77.0×10^{-6}	
Mercury		18.2×10^{-5}
Glycerin		48.5×10^{-5}
Water (0-4°C)		-3.2×10^{-5}

gives α and β values for several substances. The negative value of β for water below 4°C is anomalous and is caused by the comparatively open

lattice structure of ice. In the case of nonisotropic crystals, the coefficient of linear expansion differs for different directions in the crystals and may even have opposite signs along different directions as is the case for CaCO_3 .

Thermodynamic Relationships. The cubical coefficient of expansion plays an important role in relating the molar specific heat at constant pressure, C_P , (which is usually measured directly in the laboratory) to the molar specific heat at constant volume (which is most often obtained from theory). This relationship, based solely on the laws of thermodynamics is¹

$$C_P - C_V = (\beta^2 VT)/X \quad (3)$$

where T is the absolute temperature and X the compressibility defined by

$$X = -\frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T \quad (4)$$

To obtain this result we write the first law of thermodynamics (see THERMODYNAMICS):

$$\delta Q = dU + P dV \quad (5)$$

Since

$$C_V = \left(\frac{\delta Q}{\delta T} \right)_V = \left(\frac{\partial U}{\partial T} \right)_V \quad (6)$$

$$dU = \left(\frac{\partial U}{\partial V} \right)_T dV + \left(\frac{\partial U}{\partial T} \right)_V dT \quad (7)$$

and

$$dV = \left(\frac{\partial V}{\partial P} \right)_T dP + \left(\frac{\partial V}{\partial T} \right)_P dT \quad (8)$$

we obtain

$$\delta Q = \left[\left(\frac{\partial U}{\partial V} \right)_T + P \right] \left(\frac{\partial V}{\partial P} \right)_T dP + \left\{ C_V + \left[\left(\frac{\partial U}{\partial V} \right)_T + P \right] \left(\frac{\partial V}{\partial T} \right)_P \right\} dT \quad (9)$$

Thus

$$C_P = \left(\frac{\delta Q}{\delta T} \right)_P = C_V + \left[\left(\frac{\partial V}{\partial T} \right)_P \right] \left[P + \left(\frac{\partial U}{\partial V} \right)_T \right] \quad (10)$$

By the second law of thermodynamics, we have

$$dS = \frac{dU}{T} + \frac{P}{T} dV \quad (11)$$

On using Eq. (7) again this becomes

$$dS = \frac{1}{T} \left[\left(\frac{\partial U}{\partial V} \right)_T + P \right] dV + \frac{1}{T} \left(\frac{\partial U}{\partial T} \right)_V dT \quad (12)$$

Since

$$dS = \left(\frac{\partial S}{\partial V} \right)_T dV + \left(\frac{\partial S}{\partial T} \right)_V dT \quad (13)$$

one obtains on comparing Eqs. (12) and (13)

$$\left(\frac{\partial S}{\partial V}\right)_T = \frac{1}{T} \left[P + \left(\frac{\partial U}{\partial V}\right)_T \right] \quad (14)$$

$$\left(\frac{\partial S}{\partial T}\right)_V = \frac{1}{T} \left(\frac{\partial U}{\partial T}\right)_V \quad (15)$$

Since

$$\frac{\partial}{\partial T} \left(\frac{\partial S}{\partial V}\right)_T = \frac{\partial}{\partial V} \left(\frac{\partial S}{\partial T}\right)_V \quad (16)$$

we get from Eqs. (14) and (15)

$$\frac{1}{T} \frac{\partial^2 U}{\partial V \partial T} = \frac{1}{T^2} \left[P + \left(\frac{\partial U}{\partial V}\right)_T \right] + \frac{1}{T} \left[\left(\frac{\partial P}{\partial T}\right)_V + \frac{\partial^2 U}{\partial T \partial V} \right] \quad (17)$$

or

$$\left(\frac{\partial U}{\partial V}\right)_T = T \left(\frac{\partial P}{\partial T}\right)_V - P \quad (18)$$

Inserting Eq. (18) into Eq. (10), yields

$$C_P - C_V = T \left(\frac{\partial V}{\partial T}\right)_P \left(\frac{\partial P}{\partial T}\right)_V \quad (19)$$

Now

$$\left(\frac{\partial P}{\partial T}\right)_V \left(\frac{\partial T}{\partial V}\right)_P \left(\frac{\partial V}{\partial P}\right)_T = -1 \quad (20)$$

Thus on replacing $(\partial P/\partial T)_V$, the final form of Eq. (19) becomes

$$C_P - C_V = \frac{T \left(\frac{\partial V}{\partial T}\right)_P^2 \nu^2}{\left(\frac{\partial V}{\partial P}\right)_T \nu^2} \quad (21)$$

or Eq. (3) when the definition of compressibility [Eq. (4)] is employed.

Thus for a substance where β and χ are experimentally known C_V may be established from a measurement of C_P .

Grüneisen Relation.² Grüneisen introduced the parameter $\gamma = \beta V/\chi C_V$ and on the basis of simple models reached the conclusion that γ is independent of temperature. This implies that the thermal expansion coefficient is proportional to the specific heat and has the same type of temperature dependence. This is true for many substances and has, in fact, been employed as a means for predicting values for C_V at low temperatures. To illustrate the physical basis of the Grüneisen relation, we will work with a crystal model of N oscillators of identical frequency, ν , and each having equilibrium energy, ϵ . In the region of $h\nu \ll kT$, the free energy is given by:

$$F = N \left(\epsilon + 3kT \log \frac{h\nu}{kT} \right) \quad (22)$$

Since this must be a minimum at equilibrium, we obtain:

$$N \frac{d\epsilon}{dV} = -3NkT \frac{d(\log \nu)}{dV} \quad (23)$$

To obtain the thermal expansion coefficient, one expands $d\epsilon/dV$:

$$\frac{d\epsilon}{dV} = \left(\frac{d\epsilon}{dV}\right)_{V=V_0} + (V - V_0) \left(\frac{d^2\epsilon}{dV^2}\right)_{V=V_0} \quad (24)$$

But the compressibility is given by

$$\frac{1}{\chi_0} = NV_0 \left(\frac{d^2\epsilon}{dV^2}\right)_{V=V_0} \quad (25)$$

and thus

$$\frac{V - V_0}{V_0} = -3NkTX_0 \frac{d(\log \nu)}{dV} \quad (26)$$

Differentiating with respect to T and realizing that $3NkT$ is the thermal energy, we obtain:

$$\frac{\alpha V_0}{C_V \chi_0} = - \frac{d(\log \nu)}{d(\log V)} \quad (27)$$

More exact crystal models yield values for

$$\gamma_i = \frac{d(\log \nu_i)}{d(\log V)}$$

where ν_i is the i th frequency of a set of normal modes of vibration.³ These and other refinements give rise to modifications of the simple Grüneisen theory.

Source of Thermal Expansion. The dynamical basis for thermal expansion is the presence of an anharmonic component for the interaction potential.⁴ Taking x as the displacement of a lattice atom from its equilibrium neighbor separation, the potential energy has the form

$$V(x) = cx^2 - gx^3 \quad (28)$$

Then \bar{x} , the average displacement using the Boltzmann distribution function becomes

$$\bar{x} = \frac{\int_{-\infty}^{\infty} x e^{-V(x)/kT} dx}{\int_{-\infty}^{\infty} e^{-V(x)/kT} dx} \quad (29)$$

Assuming that the anharmonic term is much less than the harmonic contribution, we expand $V(x)$ to yield

$$\int_{-\infty}^{\infty} x e^{-1/kT} dx = \int_{-\infty}^{\infty} e^{-cx^2/kT} \left[x + \frac{gx^3}{kT} \right] dx \quad (30)$$

and

$$\int_{-\infty}^{\infty} e^{-V/kT} dx = \int_{-\infty}^{\infty} e^{-\frac{cx^2}{kT}} dx \quad (31)$$

Both integrals are readily evaluated to give

$$\bar{x} = \frac{3kTg}{4c^2} \quad (32)$$

or a constant temperature coefficient for thermal expansion. This simple derivation may be amplified to include specific interaction forces for the atoms of a lattice.⁵

Thermal Expansion and Curie Temperature. The Curie-Weiss law for both ferroelectrics and ferromagnets may be shown to be connected with the thermal expansion coefficient⁶. Consider a region where the dielectric constant, ϵ , is large. If we let N be the cell density and A a constant, the Clausius-Mosotti formula is

$$\frac{\epsilon - 1}{\epsilon + 2} = AN \quad (33)$$

Differentiating with respect to T , the temperature, and making use of the assumption that $\epsilon \gg 1$, one finds that

$$\frac{3d\epsilon}{\epsilon^2 dT} = \frac{1}{N} \frac{dN}{dT} = -\beta \quad (34)$$

On integrating between T and θ , the Curie temperature, one obtains

$$\epsilon = \frac{3/\beta}{T - \theta} \quad (35)$$

which is a typical Weiss law and indicates the Curie constant is of the order of the reciprocal of the thermal expansion. The special electronic structure of ferromagnetic materials also gives rise to anomalous thermal expansion coefficients in the transition region. For some materials β values are depressed and for others β values

increase more rapidly with temperature. Both magnetostriction and the variation of the energy of magnetization with the atomic size account for the anomalous behavior of different substances.

F

FALLOUT

The term fallout is now generally used to refer to particulate matter that is thrown into the atmosphere by a nuclear process of short time duration. Primary examples are nuclear weapon debris and effluents from a nuclear reactor excursion. The name fallout is applied both to matter that is aloft and to matter that has been deposited on the surface of the earth. Depending on the conditions of formation, this material ranges in texture from an aerosol to granules of considerable size. The aerodynamic principles governing its deposition are the same as for any other material of comparable physical nature that is thrown into the air, such as volcanic ash or particles from chimneys. However, the radioactivity associated with fallout has caused it to be put into a distinct category. This radioactivity exists because the fallout producing processes are nuclear fission and nuclear fusion.

The topographic distribution of fallout is divided into three categories called local (or close-in), tropospheric (or intermediate), and stratospheric (or world wide) fallout. No distinct boundaries exist between these categories. The distinction between local and tropospheric fallout is a function of distance from detonation to point of deposit, while the distinction between tropospheric and stratospheric fallout depends primarily on the place of injection of the debris into the atmosphere, above or below the tropopause. Whether radioactive debris from a nuclear weapon becomes tropospheric or stratospheric fallout depends on yield, height, and latitude of burst (the height of the tropopause is a function of latitude).

Because air acts as a viscous medium, a drag force is developed to oppose the gravitational force that acts on airborne particulate matter. This makes the velocity of fall dependent on particle size. The larger particles (diameters greater than about 20μ) have a higher rate of settling and create local fallout. Smaller particles injected below the tropopause are carried by prevailing winds over large regions of the surface of the earth and create the tropospheric fallout. Tropospheric fallout particles larger than about $0.1\text{-}\mu$ diameter continually mix through the circulating air mass that is in contact with the surface of the earth and gradually settle to the ground, or are washed down by rain or snow. Many smaller

particles form nuclei for raindrops. Parts of the tropospheric fallout may remain in the atmosphere for a month or more, long enough to circle the earth several times. The mean residence time above the tropopause of stratospheric fallout is from 5 to 30 months, during which time it completely encircles the earth. It gradually returns through the tropopause, primarily in certain regions where mixing between the two layers is more probable.

The exact characteristics of the radiation associated with fallout depend on the nature of the nuclear processes from which its radioactivity originates. Generally these radioactive nuclides are fission products formed from the fissioning of uranium or plutonium, but, under appropriate circumstances, considerable quantities of radioactivity can be formed through nuclear reactions induced by neutrons that are produced by the weapon or reactor. The radiation problems associated with local fallout are usually those of high-intensity gamma-ray radiation fields resulting from the relatively large quantities of radioactive material that falls back to earth within a few tens of miles from the point of origin. The important radioactive materials consist in this case of short-lived fission products and neutron-induced radioactive nuclides. The hazards of worldwide fallout come more from the problems of the long-lived radionuclides, such as Cs^{134} , Cs^{137} , and Sr^{90} , that can enter the human food chain and ultimately be absorbed by the body.

For a nuclear weapon burst in air, all materials in the fireball are vaporized. Condensation of fission products and other bomb materials is then governed by the saturation vapor pressures of the most abundant constituents. Primary debris can combine with naturally occurring aerosols, and almost all of the fallout becomes tropospheric or stratospheric. If the weapon detonation takes place within a few hundred feet of (either above or below) a land or water surface, large quantities of surface materials are drawn up or thrown into the air above the place of detonation. Condensation of radioactive nuclides in this material then leads to considerable quantities of local fallout, but some of the radioactivity still goes into tropospheric and stratospheric fallout. If the burst occurs sufficiently far underground, the surface is not broken and no fallout results.

FARADAY EFFECT

This effect was the first demonstration of a connection between magnetism and light. Faraday found in 1845 that when plane polarized light was transmitted through glass in a direction parallel to an applied magnetic field, the plane of polarization was rotated. Since Faraday's original discovery, the phenomenon has been observed in many solids, liquids, and gases. It is important in the interaction of electromagnetic radiation with the ionosphere and in the study of charge carrier behavior in the laboratory. These effects may all be regarded as acting on the electric field associated with the wave. There is a second class of Faraday rotation phenomena in which the effect acts on the magnetic-field component of the wave. These effects are very large in ferromagnetic insulators and have made possible the development of a class of nonreciprocal microwave devices, which are described briefly in the concluding paragraph. Cgs units are used throughout this article.

Electric-field Effects. Optical Rotation from Spectral Transitions. In the region of the spectrum close to an absorption line, the dielectric properties of the medium are dominated by the absorption and its associated dispersion. In those cases of interest, the absorption line is broadened or split by an applied magnetic field. One can show by quite general arguments that for every spectral component displaced linearly in the applied field, there must be a second component that is displaced in the opposite direction. The simplest case is one in which the original spectral line splits into two lines with frequencies

$$\omega^{\pm} = \omega_0 \pm \omega_L, \quad \omega^{\pm} = \omega_0 \pm \omega_L,$$

where $\omega_L = g\hbar/4mc$ is the Larmor frequency and g is called the spectroscopic splitting factor. One can again show by general arguments that in an isotropic medium, a positively circularly polarized wave will be absorbed only at ω^+ and similarly a negative wave only at ω^- . With this theoretical background, we may now consider the mechanism of rotation. Let us imagine that a linearly polarized wave at frequency ω is directed into the medium along the magnetic field. We can expect that if we decompose the incident

wave into two waves of opposite circular polarization, the waves propagate independently. Each wave is characterized by its own dielectric constant and, therefore, its own phase velocity. If the dielectric constant of the positive component is larger than that of the negative component at frequency ω , then the positive component has the lower phase velocity and is rotated through a larger angle on passing through the medium. If we recombine the waves after a path length l , we will find the plane of polarization to be rotated through an angle

$$\theta = \pi l(n^+ - n^-)/\lambda_0$$

where λ_0 is the free-space wavelength and n^+ and n^- are the refractive indices for the two polarization directions. It is occasionally inconvenient to decompose the incident field into circular components. One can alternatively characterize the medium by a dielectric tensor. The off-diagonal elements of the tensor are given by

$$\epsilon_{xy} = \epsilon_{yx} = (\epsilon^+ - \epsilon^-)/2j$$

By comparison with the earlier expression, the rotation angle may be written approximately as

$$\theta = j\pi\epsilon_{xy}l/n\lambda_0$$

For the particular case considered here we have

$$\epsilon_{xy} = 2j\omega\omega_p^2\omega_L/(\omega_0^2 - \omega^2)^2$$

where $\omega_p = (4\pi Ne^2/m)^{1/2}$ is the plasma frequency. One of the important advantages of Faraday rotation as a technique for studying optical spectra is that it permits a determination of the Larmor frequency under circumstances where it may not be possible to resolve the splitting directly. This technique is also of very considerable importance in the determination of internal magnetic fields in ferromagnetic materials.

Carrier Rotation. One can apply an analysis similar to the above in the case of free charge carriers. It is convenient to discuss the rotation by charge carriers in two limits. At frequencies low compared with the collision frequency of the carriers and to first order in the magnetic field, we obtain

$$\epsilon_{xy} = 4\pi\sigma_0\mu H/j\omega_c$$

where $\mu = e\tau/m$ is the carrier mobility and σ_0 is the low-frequency conductivity. The low-frequency Faraday effect and the Hall effect ($q.v.$) are closely related. At high frequencies the rotation is proportional to

$$\epsilon_{xy} = j\omega_c\omega_p^2/\omega^3$$

where $\omega_c = eH/mc$ is the cyclotron frequency. The Faraday effect is particularly important in the study of semiconductivity, where carriers move with an effective mass that may be considerably different from their free mass.

Magnetic-field Effects. In addition to the high-frequency Faraday effect, which is usually associated with electric dipole transitions, there are a number of low-frequency rotation phenomena, which are associated with magnetic dipole transitions. Here the rotation is associated with the tensor properties of the magnetic permeability. The rotation angle is given by

$$\theta = -j\pi\mu_{xy}/n\lambda_0$$

Paramagnetic Rotation. In a paramagnetic material the rotation is associated with the paramagnetic resonance absorption in much the same way that optical rotation is associated with optical absorption. For a paramagnetic material, the rotation is proportional to

$$\mu_{xy} = 4j\pi\chi_0\gamma H/\omega$$

where γ is the magneto-mechanical ratio.

Ferromagnetic Rotation. In a ferromagnetic material, very large rotations may be achieved because of the very large effective susceptibility $\chi_0 \gg M/H$. For magnetically saturated material we obtain

$$\mu_{xy} = 4j\pi\gamma M/\omega$$

Antiferromagnetic Rotation. Antiferromagnetic materials are characterized by resonance absorption even in the absence of a field. Applying the magnetic field along the symmetry axis we obtain

$$\mu_{xy} = 8j\pi\chi_0\omega\gamma H\omega_0^2/(\omega_0^2 - \omega^2)^2$$

where ω_0 is the zero-field resonance frequency and χ_0 is the susceptibility perpendicular to the axis.

Applications. The principal application of the Faraday effect to electronics has been in the development of nonreciprocal microwave devices. Because of the nonsymmetric character of the permeability tensor in a magnetic field, it is possible to fabricate devices that permit the nearly unattenuated passage of microwaves in one direction but will effectively block microwave transmission in the reverse direction. These devices, which make use of ferromagnetic insulators like ferrite or garnet, are of reduced effectiveness at high frequencies because of their inverse dependence on ω . Attention is being given to antiferromagnetic materials for use at high frequencies because of their increased transverse permeability in this range.

FEEDBACK

The notion of "feedback" is central to the theory of information and control, christened by the late mathematician N. Wiener in 1948 as "cybernetics," and *a fortiori* it occupies a pivotal position in the technical aspects of "automation," the latter term being coined by the American industrialist D. S. Harder in 1936. To date

"feedback," the return of "output" signals to the "input" of any device for the purpose of correcting or improving the characteristics of the device, has had greater influence within technology than within science. Within the design philosophy of modern systems, whether analogue or digital, it has become a criterion for the physical "richness" of those systems; systems not utilizing "feedback" being too simple.

The concept of the "ultrastability" of a dynamical system, i.e., the additional provision in a classical dynamical system to alter the kinds of its characteristics or to adapt to its environment, makes crucial use of secondary "feedback" to adjust other primary "feedbacks." The idea of "ultrastability," conceived by W. R. Ashby, the other principal pioneering cyberneticist, makes frequent appearance in the study of models to simulate and realize intellectual activities such as checker playing on electronic machines and theorem proving on electronic machines.

Perhaps, the oldest and simplest scheme employing "feedback" is the question-and-answer giving of ordinary conversation. If only one party does all the talking, or, more generally, all of the transmitting of signs, then there is no guarantee that the alleged message has been received, or if so, whether or not it has been understood. By continually monitoring one another, critical scientific conversation becomes possible.

Other simple, but more technical, examples of "feedback" for automatic control occur in the governor of steam engines, in thermostats, and in the automatic volume controls of radios. When more steam is fed to a steam engine its shaft accelerates. Automatic control can be realized by using a centrifugal device to tend to close off steam with greater shaft velocities. With such a scheme of "negative feedback" the engine acquires stability, i.e., it runs at an optimal velocity determined by the characteristics of the governor. On the other hand, if the centrifugal device had been installed (incorrectly) so as to supply more steam with greater shaft velocities, then this scheme of "positive feedback" would produce an instability that would either destroy the steam source or the steam engine, or both. Similarly, the automatic volume controls of radios provide "negative feedback" of a continuous or analogue variety. However, the thermostat provides "negative feedback" of a continual or discrete variety. If the local temperature exceeds a certain value, the furnace is turned off, and if the local temperature is below a certain value the furnace is turned on. Thus, unlike a steam engine and governor, the thermostat is an "on-off" device.

During and after the 1950's, even the digital computers have become components of complex sampled-data, feedback control systems. A basic idea behind sampled-data systems is that statistical sampling of signals, rather than continuous sampling, is sufficient in many cases for reliable control systems. Indeed, by the so-called Sampling Theorem, if time sampling is often enough, but not necessarily continuous, and there is an

upper bound to the electrical frequencies considered, then there is *no* loss of information.

Finally, the presently available models for the study of sequential switching circuits, which includes important parts of digital computers, all have explicit provisions for the "feedback" of informational signals.

FERMI-DIRAC STATISTICS AND FERMIONS

Solid metals are good conductors of heat and electricity because about one electron per atom is free to migrate through the volume of the conductor. These electrons were once thought to behave like gas molecules which obey Maxwell-Boltzmann statistics in which the number of particles at higher energies falls off exponentially according to a relation of the form

$$n_{E,T} = \frac{1}{e^{E/kT}}$$

where E is the energy, k the Boltzmann Constant and T the absolute temperature. This electron gas theory was qualitatively useful in explaining many metallic properties, but it was never quantitatively successful. One notable failure was its prediction that electrons should contribute to the specific heats of metals.

Bohr had shown that the electron in hydrogen is not free to assume any energy, but it is restricted to certain permitted energies called quantum states or energy levels. When this quantum view of atomic electron structure was extended to more complex atoms, it was found that electrons obey the Pauli exclusion principle—only two electrons in any one atom having oppositely directed spin can occupy the same energy state. Thus in an atom with many electrons, no more than two can have the lowest permitted energy, no more than two may have the next higher permitted energy, etc. An unexcited atom with all its electrons in their lowest possible energy states includes many electrons whose energy is well above the energy of

the lowest two. The old electron gas theory of metals recognized that the inner electrons associated with each atom were quantized but assumed that the electrons that were not bound to particular atoms were entirely free to migrate through the metal with no *a priori* restrictions on their energy. Fermi-Dirac statistics describes the behavior of the electron gas under the assumption that *all* electrons within the conductor have their energies quantized and obey the Pauli principle. This new viewpoint leads to a distribution of electron energies according to a relation of the form

$$n_{E,T} = \frac{1}{e^{(E-E_f)/kT} + 1}$$

If the metal is at high temperature, this function approaches the Maxwell-Boltzmann distribution. We can see this by noting that if $T \rightarrow \infty$, the exponent of e approaches zero regardless of E . Thus, in both cases, the number of electrons of each energy tends to become uniform. The high-temperature electrons have so many states available to them that quantum restrictions make little difference. If we let the temperature approach absolute zero, the difference between these distributions becomes extreme. If T is very small, the Maxwell-Boltzmann distribution is strongly dependent on E with most particles having low E and few having high E . Indeed for $T \rightarrow 0$, the number of particles with $E > 0$ becomes zero in a Maxwell-Boltzmann gas all particles come to rest at absolute zero. A Fermi-Dirac gas behaves very differently at absolute zero. The exponent of e is plus or minus infinity depending upon whether E is greater or less than E_f . The exponential term is either infinity or zero. The denominator is either infinity or one. All energy states below E_f are filled whereas all those above E_f are empty. Thus, consistent with the assumptions, at absolute zero the electrons do not crowd into one state of zero energy but are uniformly distributed among those states which are below the critical energy E_f called the Fermi energy or the Fermi level. Fermi energies depend on the kind of metals but they are of the order of several electron volts. Thus, even at absolute zero, some electrons have energies which would be typical of a Maxwell-Boltzmann electron gas only if that gas were at several thousand degrees.

The contrast may be dramatized by the following analogy. If grains of sand are spilled on an open floor, they will spread out so they are only one deep and each has zero potential energy. If the grains are poured into a drinking straw, the straw will fill to a certain height and some grains will have considerable potential energy.

Heating a metal from absolute zero to room temperature adds only .025 eV to the average energy of its particles. Since the electrons already have a *much* greater average energy, heating a metal has but a slight effect on the energy distribution of the electrons. This accounts for the fact that electrons make a negligible contribution to the specific heats of metals, and it also explains why metals must be glowing hot before electrons

acquire enough additional energy to escape from the metal surface as in the filaments of radio tubes. Since the quantum view of electrons in a metal provides both a qualitative and quantitative picture of many metallic properties, we know metallic electrons are quantized Fermi particles rather than unquantized Maxwell particles. The application of Fermi-Dirac statistics to semiconductors accounts for their special properties as demonstrated by transistors.

From the standpoint of wave mechanics, all particles which are confined in any way are quantized. Those whose spin is integral have symmetric wave functions and do not obey the Pauli principle. If they are so numerous that they must be treated statistically, they are called *bosons* and are described by Bose-Einstein statistics. Photons are the most common bosons. Those particles whose spins are odd multiples of $\frac{1}{2}$ have antisymmetric wave functions and obey the Pauli principle. They are called *fermions* and obey Fermi-Dirac statistics. Although electrons are the most common example, protons, neutrons, and μ -mesons are all fermions with spin $\frac{1}{2}$. At high temperatures, the quantum nature of both bosons and fermions becomes insignificant and both obey the classical statistics of Maxwell-Boltzmann. The technique of deriving these distributions is called statistical mechanics.

To convey the over-all method of STATISTICAL MECHANICS, we note that it is a probability theory in which the basic technique is to compute the number of possible ways in which a system can arrange itself subject to restrictions as to the number and total energy of the particles. These ways are all assumed equally likely. (There are $52!$ shuffles of a pack of playing cards. Each is equally likely.) Then, depending on the nature of the particles, bosons or fermions, the number of distinguishable ways is computed. (In the game of bridge, there are many fewer deals $52!/(13!)^4$, than there are shuffles because the order in which a player receives his cards does not change his "hand.") The probability of any particular distinguishable distribution is proportional to the number of ways in which it can be achieved. (If we flip a coin five times, there are $2^5 = 32$ orders in which the coin can fall. Of these, there are ten ways to get two heads and only one way to get five heads. We therefore find getting two heads ten times more probable than getting five heads.) The actual expected distribution is the one which can be achieved in the largest number of ways.

FERMI SURFACE

In simple terms, the Fermi surface of a metal, semi-metal, or semiconductor is that surface in momentum space which separates the energy states which are filled with free or quasi-free electrons from those which are unfilled. Such a surface exists simply because the electrons obey Fermi-Dirac statistics. It is a surface of constant energy and is sometimes called the Fermi level.

Consider first an elementary model of a metal consisting of a lattice of fixed positive ions immersed in a sea of conduction electrons which are free to move through the lattice. Every direction of electron motion is equally probable. Since the electrons fill the available quantized energy states starting with the lowest, a three-dimensional picture in momentum coordinates will show a spherical distribution of electron momenta and, hence, will yield a spherical Fermi surface. In this model, no account has been taken of the interaction between the fixed positive ions and the electrons; indeed the only restriction on the movement or "freedom" of the electrons is the physical confines of the metal itself.

A short derivation starting with the Schrödinger equation shows that the total energy of an electron (and thus also its kinetic energy) is given by

$$E = \hbar^2 k^2 / 2m = p^2 / 2m$$

where \hbar is Planck's constant divided by 2π , k is the magnitude of the electron wave vector, m is the mass of the electron, and p is its momentum. A plot of E against k is then a parabola, as shown in Fig. 1(a). The Cartesian components of those values of k which are possible solutions to the Schrödinger equation are $k_i = 2\pi n_i / L$, where the n_i 's are integers and L is a physical dimension of the metal. Since for each energy value so defined there are actually two states (one for an electron with spin up, one with spin down), it can be shown that the density of energy states available to the electrons is

$$g(E) = \frac{(2m)^{3/2}}{2\pi^2 \hbar^3} E^{1/2}$$

where $g(E) dE$ is the number of states in the energy range E to $E + dE$. Then $n(E)$, the number of electrons per unit volume occupying energy states in this energy range, is

$$n(E) dE = g(E) f(E) dE$$

where $f(E) = \{\exp[(E - E_F)/kT] + 1\}^{-1}$, a function characteristic of particles which obey Fermi-Dirac statistics. In this expression, T is the absolute temperature, k is Boltzmann's constant, and E_F is a parameter depending on the number of electrons involved and indeed turns out to be the Fermi energy. E_F can be evaluated by integrating $n(E) dE$ from $E = 0$ to $E = \infty$ and recognizing that the integral is equal to N , the total number of electrons per unit volume. The result (at $T = 0$ K) is

$$E_F = \frac{\pi^2 \hbar^2}{2m} \left(\frac{3N}{\pi} \right)^{2/3}$$

FIG. 1 (a) Energy plotted against wave number for the free electron model. (b) Energy plotted against wave number for the "quasi-free" electron model, showing energy discontinuities at Brillouin zone boundaries.

At $T = 0^\circ \text{K}$, for $E < E_F$, $f(E) = 1$, while for $E > E_F$, $f(E) = 0$. Physically this means that the probability of a state below the Fermi level being occupied is one; whereas for states with $E > E_F$ the occupancy probability drops abruptly to zero. For temperatures greater than absolute zero, the occupancy probability drops smoothly from 1 to 0 in a range of energy of width approximately equal to kT . This shell of partially filled states gives rise to the following definition: The Fermi level is the energy level at which the probability of a state being filled is just equal to one half.

A numerical evaluation of the Fermi energy for a simple metal having one or two conduction electrons per atom yields a value of approximately 10^{-11} erg, or a few electron volts. The equivalent temperature, E_F/k , is several tens of thousands of degrees Kelvin. Thus, except in extraordinary circumstances, when dealing with metals, $kT \ll E_F$; i.e., the energy range of partially filled states is small, and the Fermi surface is well defined by the statement above. It must, however, be noted that this is not necessarily true for semiconductors where the number of free electrons per unit volume may be very much smaller.

The foregoing treatment gives a qualitative insight into the physics of metals and, under some circumstances, semi-metals and semiconductors. A more detailed analysis requires that the effects of the ions in the lattice be recognized. This can be accomplished by introducing the periodic potential due to the lattice through which the electrons must move. Then the electrons are no longer "free," but, depending on the strength and character of the potentials and the approximations used in solving the Schrödinger equation, act as "quasi-free" particles. Another approach is the "tight-binding approximation"; occasionally a combination of the two approaches is used. In any case, introduction of lattice effects changes the characteristics of the model; the total energy and kinetic energy of an electron are no longer equivalent. The periodic lattice can be described conveniently in terms of Brillouin zones, each of which is large enough (in momentum space) to accommodate two electrons per atom. The Brillouin zone boundaries appear to the electrons as Bragg reflection planes or energy discontinuities, resulting in an energy versus wave number plot as shown in Fig. 1(b).

For many metals, the "nearly free" electron description corresponds quite closely to the physical situation. The Fermi surface remains nearly spherical in shape. However, it may now be intersected by several Brillouin zone boundaries which break the surface into a number of separate sheets. It becomes useful to describe the Fermi surface in terms not only of zones or sheets filled with electrons, but also of zones or sheets of holes, that is, momentum space volumes which are empty of electrons. A conceptually simple method of constructing these successive sheets, often also referred to as "first zone," "second zone," etc., was demonstrated by Harrison.¹ An example of such a construction is shown in Fig. 2. This construction works quite well, for example, for aluminum which has three valence electrons per atom. Experiments, and indeed more elegant theoretical calculations, show that the fourth zone is totally unoccupied and that the third zone monster is not multiple-connected in the manner shown. The recipe for constructing these figures, some of which may even be pleasing to art connoisseurs, cannot be developed in the limited space of this article but will be found in the references.^{1,2}

The intense research effort of the last decade on the Fermi surfaces of metals and semi-metals originated, to a great extent, with Pippard's ingenious deductions, based on anomalous skin-effect experiments, concerning the Fermi surface of copper.³ Prior to Pippard's work, it was taken for granted that in copper, with one quasi-free electron per atom, the first Brillouin zone would be only half filled and, hence, would have a nearly spherical Fermi surface. His work suggested that a series of eight necks pull out and touch the Brillouin zone boundaries in the $[111]$ crystallographic directions. This shape has now been confirmed and precisely mapped, not only for copper but also for silver and gold.

FIG. 2. Fermi surfaces in several zones or bands, for face-centered cubic metals having various numbers of "quasi-free" electrons per atom, as constructed by Harrison.¹

A variety of experimental techniques have been developed, capable of yielding both overlapping and complementary information concerning Fermi surfaces of metals and semi-metals. Listed below are some of these and the features of the Fermi surface they measure:^{1,5}

- (1) de Haas-van Alphen effect: extremal cross-sectional areas of the Fermi surface;
- (2) Cyclotron resonance: surface curvature and effective masses;
- (3) Magnetoacoustic effect: extremal linear dimensions;
- (4) Magnetoresistance: areas of contact with Brillouin zone boundaries;
- (5) Anomalous skin effect: surface curvature and surface area;

- (6) Positron annihilation: number of electrons in a given cross section;

- (7) Gantmakher effect: extremal linear dimensions.

The precision and applicability of each of these techniques is dependent on the material under investigation. Among pertinent factors are number of quasi-free electrons per atom, crystallographic structure, magnetic properties, purity, and practicality of sample preparation.

Paralleling this experimental work has been a good deal of theoretical activity. Attention has been concentrated on the calculation of Fermi surfaces for a number of metals and semi-metals, most frequently through the use of orthogonalized or augmented plane wave techniques and studies

of the theoretical bases for the interpretation of the experimental data.

FERRIMAGNETISM

Snoek's publication (1946) of his wartime work on ferrites established the existence of new ceramic magnetic materials capable of combining the resistivity of a good insulator (10^{12} ohm-cm) with high permeability. (see MAGNETISM.) In 1948, Néel introduced the term ferrimagnetism to describe the novel magnetic properties of these materials. A simple ferrite is composed of two interpenetrating FERROMAGNETIC sublattices with magnetizations $M_a(T)$ and $M_b(T)$ which decrease with increasing temperature and vanish at the Curie point, T_c . In a ferromagnetic material, the resulting saturation magnetization, M , would be $M_a + M_b$; however, in a ferrite, strong antiferromagnetic interaction between sublattices results in antiparallel alignment, and $M = M_a - M_b$. In general $M_a(T) \neq M_b(T)$, and the material behaves in most respects like a ferromagnet, exhibiting domains, a hysteresis loop, and saturation of the magnetization at relatively low applied magnetic fields. Practical values for saturation magnetization and Curie temperature range from 250 to 5000 oersteds and from 100 to 600 C. The high resistivity of ferrites led to early applications in low-loss coil and TRANSFORMER cores. Some ferrites display a rectangular hysteresis loop. This property has been used extensively in binary switching and memory devices.

Ferrimagnetic materials have spinel, garnet, and hexagonal structures. A typical spinel ferrite is NiFe_2O_4 . Other ferrites may be obtained by substituting magnetic (Co, Ni, Mn) or non-magnetic (Al, Zn, Cu) ions for some of the Ni or Fe ions, e.g., $\text{Ni}_{1-x}\text{Co}_x\text{Al}_2\text{Fe}_{2-x}\text{O}_4$, where x and y may be varied to modify M and T_c . Yttrium iron garnet (YIG), $\text{Y}_3\text{Fe}_5\text{O}_{12}$, is the classical ferrimagnetic garnet which combines very low magnetic loss with high resistivity. Substitution of magnetic RARE EARTH ions (Gd, Yb, Ho, etc.) for Y and of nonmagnetic ions (Ga, Al) for some

of the Fe ions leads to many different ferrite compositions with a wide range of M and magnetic loss. The rare earth ions form a third magnetic sublattice with attendant magnetization M_c antiparallel to the resultant magnetization $M_{a,b}$ of the two Fe sublattices. Since M_c and $M_{a,b}$ exhibit different variations with temperature, the net magnetization may vanish twice, at T_c and at an intermediate temperature called the compensation point, T_{comp} , where $M_c = M_{a,b}$.

A typical hexagonal ferrite is $\text{BaFe}_{12}\text{O}_{19}$. Again, other magnetic ions such as Mn, Co, and Ni may be introduced to produce wide variations in M and T_c . Hexagonal ferrites are characterized by large anisotropy fields with an axis of symmetry which may be either a direction of hard (planar ferrites) or easy (uniaxial ferrites) magnetization. They have been used as permanent magnets, in harmonic generators, and in millimeter microwave devices.

All microwave ferrite devices such as isolators, circulators, switches, phase shifters, limiters, parametric amplifiers, and harmonic generators are based on interactions of rf signals with the ferrite magnetization. Aligning M with an external biasing magnetic field, H_{dc} , and applying a microwave signal in an orthogonal direction leads to strong interaction and gyromagnetic resonance. On a microscopic scale, this is explained as application of a torque to the unpaired ELECTRON SPINS of the magnetic ions which causes them to precess at the rf frequency much like so many spinning tops. The precessional motion has a microwave RESONANCE frequency f_r dependent upon H_{dc} and the gyromagnetic splitting factor g_{eff} . In ferrimagnets with spinel structure, g_{eff} is related to the g -factors of the sublattices as follows:

$$g_{\text{eff}} = M / [(M_a/g_a) - (M_b/g_b)]$$

On a macroscopic scale, this interaction modifies the rf magnetic field in a manner which is described by introducing an antisymmetric permeability tensor $[\mu]$ whose complex components depend on M , H_{dc} , and frequency. When the frequency approaches f_r , one observes a resonance absorption line whose width, ΔH , is determined by the magnetic loss of the material. Values for ΔH cover a range from ~ 1 oersted for single-crystal YIG to ~ 1000 oersteds for some polycrystalline Ni-ferrites. The interaction of rf fields and electron spins becomes a maximum if the rf field is circularly polarized in the same sense as the precessional motion of the spins. Circular polarization in the opposite direction produces almost no interaction and no gyromagnetic resonance. This permits design of nonreciprocal ferrite devices. At high levels of microwave power, nonlinear coupling between microwave signal and precessional spin motion causes the parametric excitation of higher order modes of spin motion (magnetostatic modes and spin waves). This effect has been exploited in limiters and parametric amplifiers.

FERROELECTRICITY

Ferroelectricity is defined most reasonably as follows: When a crystal plate, in some direction, of a crystal has two stable states (different in polarization) at zero electric field and is capable of alternating between these states by means of a suitable alternating electric field, the crystal plate or the crystal is said to be ferroelectric; here, the two stable states are assumed to be identical or enantiomorphous in crystal structure and to be equal in plate thickness. In this definition of ferroelectricity, the phrase "different in polarization" is omissible, since this naturally follows from the postulate that the state transition is brought about by an electric field. If the two states were equal in polarization, the electric field would not do any work at the state transition, which means impossibility of the state transition by the electric field.

From the definition, it is concluded that any ferroelectric crystal must crystallographically belong to a noncentrosymmetric point group. Moreover, it is reasoned that the ferroelectric crystals belonging to the nonpolar (but non-centrosymmetric) groups are hardly expected to exist; in fact, none of them have yet been discovered actually. (It is not concluded that every ferroelectric crystal must belong to a polar group.)

A ferroelectric crystal is said to be regular when (1) in any crystal plate (with any Miller indices) of the crystal, the space lattice in one of the two stable states is parallel to the space lattice in the other and (2) the notion of the two stable states is possible not only for the individual crystal plates but for the crystal as a whole. From this definition, it is deduced that the regular ferroelectrics must belong to the polar groups. In general, a ferroelectric crystal belonging to a polar group satisfies the second condition for regularity if it satisfies the first condition. Therefore, the regular ferroelectrics can also be re-defined as the ferroelectrics which belong to the polar groups and satisfy the first condition, i.e., the condition of lattice parallelism. A ferroelectric crystal is said to be irregular when it is not regular. As examples, triglycine sulfate is regular and Rochelle salt is irregular.

For every ferroelectric crystal plate, it is possible to prove the existence of a spontaneous polarization P_s which must be independent of the way of choosing the reference structure (or the unit cell) and the way of emergence of the crystal-plate boundaries: P_s is equal to half the difference between the polarizations which the crystal plate shows in the two states at zero electric field.

Furthermore, for every regular ferroelectric crystal, it is possible to prove the existence of a spontaneous polarization *vector* which must be independent of the reference structure (or the unit cell), the crystal-plate orientation, and the crystal-plate boundaries. The spontaneous polarization P_s of a crystal plate, in a direction \mathbf{n} , of a regular ferroelectric crystal is equal to the component in that direction of the spontaneous polarization vector \mathbf{P}_s of the crystal: $P_s = \mathbf{P}_s \cdot \mathbf{n}$. It is only the regular ones which possess such a spontaneous polarization vector. (Existence of a spontaneous polarization is not to be supposed *a priori* in the definition of ferroelectricity, but is to be proved *a posteriori*.)

The regular and the irregular ferroelectrics are divided into fourteen and eleven kinds, respectively, in accordance with their point groups, space lattices, and types of state transition; thus, all ferroelectrics are divided into 25 kinds. (Here, the ferroelectrics belonging to the nonpolar groups are left out of consideration.) The fourteen regular kinds are denoted by the symbols

$$\begin{aligned} & \epsilon 1, rm, r2, rmm2, r4, r4mm, \\ & r6, r6mm, r3R, r3mR, \\ & r3P-I, r3P-II, r3mP-I, r3mP-II. \end{aligned}$$

The eleven irregular kinds are denoted by the symbols

$$\begin{aligned} & i1-I, i1-II, im, i2-I, i2-II, imm2, \\ & i4, i6, i3R, i3P-I, i3P-II. \end{aligned}$$

(For the meaning of each symbol see refs. 2 and 3.) If one knows the kind of a ferroelectric, one can deduce the (macroscopic and microscopic) characteristics of the ferroelectric in one state from the information about the other state and can, moreover, make some predictions on the phase transformation of the ferroelectric to a paraelectric phase.

A crystal is called paraelectric when it is not ferroelectric. This concept of paraelectricity is the broadest. Sometimes, the antiferroelectrics are separated from the paraelectrics. The notion of antiferroelectricity differs more or less from person to person. A most reasonable one is the following: A paraelectric crystal (in the general sense) is said to be antiferroelectric when by means of an electric field it can transform to another phase of whose lattice the original lattice becomes a superlattice. In this definition, one need not care about the dielectric nature of the induced phase (although usually it is regarded as ferroelectric).

FERROMAGNETISM

Ferromagnetism is an example of cooperative phenomena in solids. It is characterized by a spontaneous macroscopic magnetization M (magnetic moment per unit volume) in the absence of an applied magnetic field at temperatures below a critical value known as the Curie temperature, T_c . This property is exhibited by the transition metals, Fe, Co, and Ni; the rare earth metals, Gd, Tb, Dy, Ho, Er, and Tm; and by a variety of alloys, compounds, and solid solutions involving the transition, rare earth, and actinide elements. Ferromagnetic Curie temperatures range from a fraction of a degree to hundreds of degrees Kelvin.

Cooperative magnetic behavior results from the exchange interaction between electrons which is qualitatively described as follows. Electrostatic coulomb repulsion between like electric charges acts to keep two electrons apart, a separation which is also favored by the Pauli exclusion principle if the electrons have parallel spins. Thus if two electrons are farther apart when their spins are parallel than they would be if their spins were antiparallel, the parallel state will have lower mutual electrostatic energy. However, the kinetic energies increase if the electrons are separated, and consideration of this energy may lead to lower total energy for antiparallel spins. In other words, the exchange interaction is electrostatic in nature, but is modified by details of kinetic energy and the exclusion principle, and is highly dependent on the spatial distribution of the electrons. The exchange energy between two electrons, though electrostatic, is usually expressed in the mathematically equivalent form, $-2Js_1 \cdot s_2$, where s_1 and s_2 are the spin angular momentum vectors of the two electrons. When J is positive, parallel spins represent a lower energy state than antiparallel spins. Since each electron has a magnetic moment proportional to its spin angular momentum, a state of parallel spins corresponds to a state of parallel magnetic moments.

The principal effect of the exchange interaction is embodied in the empirical Hund's rules which describe the combination of electron spins in an atom to form the atomic spin. The principal interaction between magnetic atoms, i.e., between atoms with a magnetic moment as a consequence of spin angular momentum, is thought to be of exchange character also and there has been considerable success in describing magnetic properties by assuming this interaction to have the form,

$$\mathcal{H} = - \sum_{i,j} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j.$$

Here \mathbf{S}_i and \mathbf{S}_j are the spin angular momentum vectors of atoms i and j ; the exchange integral, J_{ij} , may vary for different pairs and is usually regarded as a phenomenological parameter to be evaluated by means of experimental data. When J_{ij} is positive, parallel ordering or alignment of the atomic spins in a common direction is favored, and so there is a large spontaneous magnetization

even in the absence of an applied field. For negative J_{ij} , antiparallel spins result in lower energy (see ANTIFERROMAGNETISM, FERRIMAGNETISM).

Maximum ordering obtains at the absolute zero of temperature where the randomizing effect of thermal agitation disappears. The initial decrease of the magnetization as the temperature is increased from zero is well represented by a superposition of wavelike disturbances known as spin waves. At the Curie temperature the magnetic ordering is destroyed by thermal agitation and the spontaneous magnetization is zero (Fig. 1). Above the Curie temperature a ferromagnetic material behaves paramagnetically and has a net magnetization only in the presence of an applied field (see MAGNETISM and PARAMAGNETISM).

FIG. 1. Typical variation of spontaneous domain magnetization, M_s , as a function of temperature, T .

At temperatures below T_c a sample of ferromagnetic material is usually divided into small regions called domains, which vary in size and shape with a typical dimension from 0.1 to 1000 μ . Within each domain the magnetization is uniform and has the maximum or saturation value, M_s , characteristic of the temperature of the material (Fig. 1), but the direction of alignment of the individual moments in each domain changes from one domain to the next. The magnetization of the sample, which is the resultant of the magnetization of all the domains, may be much less than the saturation value (of a single domain), or it may even be zero in a completely demagnetized state.

The magnetization of a sample increases when a magnetic field, H , is applied. The value of H required to saturate the magnetization may be as small as 0.01 oersted or as large as several thousand oersteds, depending on the material. The magnetization process for a previously demagnetized material is represented by the 0-to-a portion of the magnetization curve in Fig. 2. When the applied field is subsequently

FIG. 2. Typical variation of sample magnetization, M , as a function of applied field strength, H ; the magnetization curve depends on the magnetic history of the sample.

removed, the magnetization exhibits the phenomenon of hysteresis, or lagging behind, tracing the path a-b and retaining a finite value, called the remanence, when the field is zero. The coercive force is the value of the field which must be applied opposite to the direction of the magnetic moment to trace the path b-c and reduce the magnetization to zero. Further increase of the field in this direction, followed by its removal, traces the path c-d-e. Repetition of the cycle then traces the curve e-f-a-b-c-d-e, etc. Permanent magnets are characterized by a large coercive force; i.e., a large reverse field (typically thousands of oersteds) is necessary to destroy the magnetization. However, in soft magnetic materials the coercive force may be less than one oersted.

Domains exist in a ferromagnetic material because their formation results in a lower total energy for the sample than it would have if the entire sample were a single domain. Total alignment of the magnetic moments is favored by the exchange forces, but these are usually short range forces acting between an atom and its neighbors. The dipole-dipole forces, although weaker, are long range and, alone, would orient the atomic moments like bar magnets, north pole to south pole, in closed chains to minimize the external field of the magnet (see **DIPOLE MOMENT AND MAGNETISM**). One additional factor is required for the formation of domains. This factor is anisotropy, a result of the crystal structure of most solid materials. The structure of a crystal is not the same in all directions; consequently its physical properties depend on direction. It is easier to magnetize a magnetic material in some directions, called easy axes, than in other directions. When the effect of anisotropy is superimposed on the effects of exchange and dipolar coupling, the ordered atomic moments break up

into segments or domains, so that in each domain the magnetization is uniform and lies along or near one of the easy axes. There is a large change in the direction of magnetization from one domain to the next, with the reorientation occurring gradually (on an atomic scale) in a narrow transition region known as the domain wall.

FIG. 3 Schematic representation of the change of domain structure and magnetization with applied field.

The initial part of the magnetization process, 0-a in Fig. 2, is represented schematically in Fig. 3. In the demagnetized state the domains are arranged to minimize the external field due to the magnetization and to give zero net moment for the sample (Fig. 3a). In low fields the domain boundaries move so that the domains with magnetization direction near the direction of the applied field grow in size while other domains are depleted (Fig. 3b). As the field strength is increased, the domain boundaries are swept out of the sample (Fig. 3c), and finally the (single) domain magnetization rotates into the direction of the applied field until saturation is reached (Fig. 3d). When the field is removed, domains re-form in varied orientation along the easy axes, but there is a preference for domains whose magnetization vectors lie in the easy directions nearest the direction in which the field was applied, and consequently the sample as a whole has a magnetic moment (remanent magnetization).

FIELD EMISSION

Field emission of electrically charged particles occurs when a sufficiently high electric field is applied to the surface of a conductor. Specifically, field emission of electrons from cold metals into a vacuum is a basic physical effect comparable to thermionic, photoelectric, or secondary emission. Field electron emission is also termed "cold emission" or "autoelectronic emission." Field emission of electrons from metals at room temperature requires an electric field of an order of magnitude of 3×10^7 volts/cm which can be obtained by applying a few thousand volts to a sharply curved cathode, which may be either a fine wire, a sharp edge, or a needle tip. From such cathodes, field emission was first observed by R. W. Wood in 1897, and technical application in high-voltage rectifiers and x-ray tubes was attempted by J. E. Lilienfeld in the early 1920's. He failed because of the inadequate vacuum techniques available at that time. The quantum mechanical theory of field emission was given by R. H. Fowler and L. W. Nordheim in 1928 which agreed with the current-voltage relationship measured by R. A. Millikan and C. C. Lauritsen, but experimental work to further verify the predictions advanced only with the possibility of controlling highly perfect emitter tips in the field emission microscope by E. W. Müller, 1937. Subsequently, field emission microscopy became an established research technique for surface phenomena connected with adsorption. By operating a point emitter at a positive potential in the presence of a gas, Müller discovered field ionization (1951) and developed the low-temperature field ion microscope (1956) which surpasses all other microscopic devices with its capability of showing the individual atoms as they constitute the crystal lattice of the metal specimen. In the last decade, technical application of field emission has also been successful with the development of powerful flash x-ray tubes (W. P. Dyke, 1955). The extremely large current densities of up to 10^8 amperes/cm² make a field emission cathode very attractive for mm wave tubes, cathode ray tubes, and electron microscopes, but the sensitivity to contamination and cathode sputtering are detrimental to stability and long lifetime.

Field emission can be explained with the concepts of quantum mechanics. The conduction electrons of a metal are moving in a potential trough, from which they can escape ordinarily only by addition of thermal energy (thermionic emission), by an energy transfer from photons (photoelectric emission), or by collision with other energetic particles (secondary emission). If the

barrier of the trough is narrowed by the application of an external electric field to be comparable with the wavelength of the electrons inside the metal, then a small amplitude of the electron wave will be noticeable outside the barrier, or in an equivalent interpretation, there is a finite probability of the electron penetrating through the potential barrier, even if its kinetic energy is insufficient to go over it. According to the Fowler-Nordheim theory of field emission, the current density J (in amperes/cm²) as a function of field strength F (volts/cm²) and of the work function ϕ (electron-volts) is approximately given by

$$1.55 \cdot 10^{-8} \frac{F^2}{\phi} e^{-\frac{6.85 \cdot 10^7 \phi}{F}}$$

A more refined theory takes into account the effect of the image force on the electron, which reduces the exponent of the above equation by a factor slightly smaller than unity and which depends upon ϕ/\sqrt{F} . The field required for a given current density is thus reduced by some 10 to 20 per cent. The temperature dependence of field emission is found to be very small below about 1000° K (Fig. 1). Considerable increase in emission is observed when both the temperature and the field are high. This effect is called T - F emission.

FIG. 1. Current density of field emission for a tungsten cathode plotted as a function of reciprocal field strength, for various temperatures.

Field emission of positive ions can occur when an adsorption layer is removed from the positive emitter tip by the electric field (field desorption, Müller, 1941) or at still higher field strength when the metal atoms of the emitter are coming off after single or double ionization (field evaporation, Müller, 1956). These ion currents are only transients since the source of the ions one

monoatomic adsorption layer or the tip surface itself, is soon consumed. Continuous field ion emission is obtained by operating the positive emitter in a gas of low pressure. Gas molecules attracted to the tip surface by polarization are ionized when their valence electron tunnels out into the metal while the molecule is a few angstroms above the surface. Ion currents are small (less than 10^{-8} ampere) due to the limited supply of the gas molecules, and the fields necessary for ionization are very high, about $2.5 \cdot 10^8$ volts/cm for hydrogen and $4.5 \cdot 10^8$ volts/cm for helium.

In spite of its limited technical application, field emission has been a subject of intensive investigations, and the field electron and the field ion microscopes have become productive tools of basic research in the study of metal surfaces. The specimen of the field emission microscope is a needle-shaped field emitter with a hemispherical tip of a radius of some 10^{-5} to 10^{-4} cm, arranged in a vacuum tube opposite to a fluorescent screen. With a few thousand volts applied, field emitted electrons move away from the tip in a radial direction, displaying on the screen an enlarged projection image of the distribution of electron emission at the emitter. The magnification of this microscope is approximately equal to the ratio of screen distance to tip radius and can exceed a million diameters. The lateral resolution is limited to 25 \AA by a random tangential velocity component of the electrons due to the Fermi distribution inside the metal and by diffraction due to the de Broglie wavelength. As even traces of adsorption layers change the work function and, thereby, the emission, the presence of such layers can be readily detected on the screen. The imaged tip cap usually represents a single crystal, so that the behavior of adsorption layers can be studied in its dependence on crystallographic orientation of the substrate. As little as 10^{-3} of a monolayer of oxygen is clearly discernible on many metals. Because of the small temperature dependence of field emission, such layers, their surface migration, adsorption and desorption rates, and the activation energies of these processes can be measured in a wide temperature range. This is done by immersing the entire microscope into a cryogenic bath and by heating the emitter to any desired temperature up to near its melting point. Most studies have been done with the high-melting metals, W, Re, Ta, Mo, Nb, Ir, Pt, Rh, Pd, V, Ni, Fe, Ti, Cu, and various alloys and with adsorption layers of H_2 , N_2 , O_2 , CO, CO_2 , and the noble gases. Detailed patterns of individual organic molecules, such as phthalocyanine or smaller aromatic compounds, cannot yet be fully explained. The interpretation of thermal desorption experiments is often difficult because of the occurrence of surface migration, while the well-defined field strength obtained in field desorption experiments cannot be fully utilized because of the complex polarization conditions at the various adsorption sites.

The field ion microscope (Fig. 2) was developed to overcome the limitation of resolution of the field electron microscope. In contrast to the case

FIG. 2. Schematic diagram of a demountable field ion microscope. The hemispherical cap of the tip, having a typical radius of 500 \AA , is radially projected onto the fluorescent screen with the help of helium ions.

of electrons, the undesirable tangential motion of the imaging ions can be reduced by lowering the emitter temperature. The shorter de Broglie wavelength of ions is also an advantage. Usually operated with helium as the imaging gas and the tip cooled by liquid nitrogen, or better by liquid hydrogen, the ions image the field distribution over the emitter tip in a resolution of up to 2.5 \AA (Fig. 3). The specimen is atomically cleaned and shaped to an evenly curved, highly perfect surface by field evaporation. Helium atoms ionize above each atomic protrusion of the specimen and are then accelerated towards the screen. Each protruding surface atom is imaged by about 10^5 helium ions/sec. The surface stays atomically clean as all impurity gases have a lower ionization potential than helium and thus are ionized in the lower field region in space before they can reach the tip. Vacuum requirements are, therefore, very modest, and an unbaked demountable system can be used. Image stability requires that the evaporation field be above the ionization field of the imaging gas. Field ion microscopy with helium is, therefore, limited to the refractory metals. Using lower ionization potential gases, such as Ne, Ar, or H_2 , imaging with some loss of resolution can be done with reduced fields, and the common transition metals become accessible. Extremely low image intensity and the instability of the surface near the evaporation field can be partly overcome with the use of photoelectronic image intensification. The

FIG. 3. Field ion micrograph of a platinum-cobalt alloy crystal (50 per cent, ordered at 700 C), showing the individual atoms as single dots. Original magnification on the 5-inch screen was 1.5 million diameters.

most promising application is the direct observation of lattice imperfections in metal crystals. Single vacancies produced by quenching, cold working, or irradiation can be counted. Interstitials resulting from radiation damage can be seen; their thermal migration to the tip surface can be measured. The core structure of dislocations and the match of the lattices along grain boundaries can be seen in atomic details, including their interaction with impurity atoms. Controlled field evaporation permits the removal and inspection of subsequent surface layers, so that the depth of the crystal can be searched for defects. The high mechanical stress $F^2/8\pi$ of the field, amounting to nearly 1 ton/mm² at the helium imaging field, can influence the defect structure of the specimen, and it can also be utilized for the study of slip bands and fatigue. To a limited extent, short-range and long-range order in alloys can be studied, although it is difficult to distinguish between the constituents. The first stages of corrosion by adsorbed gases and the

polarization modified adsorption sites of individually visible gas molecules are other promising subjects of field ion microscopy.

FIELD THEORY

The description of the physical world has evolved profoundly through the ages, at times because of, at other times being the cause of, sweeping changes in our philosophical, mathematical and experimental knowledge. Greek geometry concerned itself essentially with properties of "objects as such," a triangle or a cube being studied, for example, without any thought of their spatial environment; the Ptolemaic system enhanced this view into a clockmaker's dream, where celestial bodies parade around the earth, rigidly driven in circular motions. Only with Descartes' analytical geometry did objects become "portions of space" and the properties of space itself the main object of study; with Galileo and Newton, a correct science of dynamics was born, which permits the prevision of an amazing number of mechanical phenomena in that space from a few first principles.

Field theory studies the phenomena of the physical world as due to interactions which propagate through space; the "geometrical emptiness," which is the space of mathematics, becomes the medium into and through which actions take place or, even more drastically, a structure which is itself determined by the properties of matter, as in general relativity (which will not be discussed in this article).

Suppose two bodies interact in space, e.g., the sun and the earth with Newton's law, or two electric charges with Coulomb's law. Two pictures of this situation are equally possible and correct. One is that this interaction cannot be conceived if *both* bodies are not there and that we should study primarily its effects without looking for a detailed mechanism for its propagation from one body to the other; this is the description of "action at a distance", in which *forces* are the main concepts and space is a vacuum into which bodies follow trajectories determined by the forces acting upon them. The other picture consists in imagining that each body, whether alone or not, modifies the structure of the space which surrounds it, geometrically or because in each point of that space there is now potentially a force, which becomes active if another body occupies that point, but should be conceived as existing there in any case; the main objective is here to study how these "fields of force" are created in space by material objects and how they propagate; this is the point of view of "action with contact," which finds its full development in field theory.

Mathematically, a field is characterized by assigning to each point of space a quantity which is *intrinsically* associated with it; a temperature, for instance, or a velocity, or a tensor or a spinor of arbitrary rank. "Intrinsic" means that if we change our frame of observation, this quantity does *not* change; supposing, e.g., that our field is that of the velocities at a given instant of all the points of a moving fluid, if we rotate our coordinate system we shall observe different values for the components of those velocities, just

because we, not the velocities, have changed position. It is therefore essential that, together with the specification of the field quantities, their transformation laws also be assigned under changes of the reference frame; these laws are indicated by the description of the field quantity as a "scalar" (which does not change), a "vector" (which changes with the same law as the coordinates), a "tensor," etc.; the complete specification of all such possible laws is a standard chapter of group theory.

Physically, we have to account for the creation or the existence of the field, by describing the field quantities as generated by "sources," such as positive or negative charges for the electromagnetic field, or the sources and sinks of hydrodynamics. Moreover, we have to describe in which way the values of the field quantities change when the point at which they are considered, or the time, is changed. In the absence of discontinuities, for instance in vacuum, one expects these values to differ by infinitesimal amounts if the corresponding points are infinitesimally close, in some way which is typical of the field considered; in other words, that the rates of change of the field quantities with respect to the space coordinates and time be connected by relations which specify both how these changes can occur compatibly with the geometrical properties of space, and how they are related to the sources. Group theory determines all the possible forms which are permissible for these relations, which take the name of *field equations*; each field theory is characterized by a special set of field equations, which are clearly *partial differential equations*.

RELATIVITY and QUANTUM THEORY have played a great rôle in the development of field theory; we shall briefly discuss, later, their influence both in the explanation of new physical phenomena and in the mathematical formulation of the theory.

Field theory has taken an entirely new shape with the so-called second quantization, which has led to several modern developments, of which some embody faithfully the concepts outlined thus far and others instead represent new views in natural philosophy; this is still a matter of controversy at present, and it is yet unpredictable whether a reasonably lasting description of nature will come out of such attempts or whether a new drastic turn in human thought will be necessary before we can hope to understand the fundamental laws of physics. Be that as it may, the ideas and the computational techniques of field theory have proved already of invaluable help in the description of many phenomena, from particle physics to superconductivity.

It is convenient to examine first the theories in which the field quantities are ordinary functions of space and time points, regardless of whether they have a direct physical meaning (as with the velocities of hydrodynamics and the electromagnetic forces) or not (as with the wave function which obeys a Schrödinger equation). This comprises of course most of classical and modern physics; mathematics permits again,

however, a tremendous conceptual simplification. In the study of continuous media or fields one is, most often, interested in one of the following classes of phenomena:

(1) Phenomena which consist of the propagation of some action; the medium itself is not transported from one place to another; typical is the propagation of waves, whether they be seismic, fluid or electromagnetic;

(2) Phenomena in which there is transport or diffusion of a quantity in a medium: of heat in a wall, of solute in a solvent, of neutrons in a pile;

(3) Equilibrium phenomena: deformations of strained elastic bodies, electro- or magnetostatic fields as determined by charges and boundaries.

Each class is ruled by essentially one type of equation. Let $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2$ denote the Laplace operator; $\phi = \phi(x, y, z, t)$ the field quantity; F some function of x, y, z, t, ϕ and, at most, of the first-order derivatives of ϕ ; v a velocity; and D a diffusion constant. The corresponding equations can be brought into the standard forms:

$$\Delta\phi - \frac{1}{v^2} \frac{\partial^2 \phi}{\partial t^2} = F \text{ (hyperbolic partial differential equation) (1)}$$

$$\Delta\phi - \frac{1}{D} \frac{\partial \phi}{\partial t} = F \text{ (parabolic partial differential equation) (2)}$$

$$\Delta\phi = F \text{ (elliptic partial differential equation) (3)}$$

If the field quantity has more than one component, one may deduce for each of its components an equation which is essentially of the same type, although it may be difficult or impossible to obtain an independent equation for each component.

This classification of physical phenomena according to the type of equation to which their study can be reduced is of the greatest importance: Eqs. (1), (2) and (3) are called in fact "the equations of mathematical physics"; more specifically, Eq. (1) is also called the wave equation, Eq. (2) the heat equation, and Eq. (3) the Laplace or potential equation. The study of their mathematical properties gives complete information on all the physical phenomena which they describe.

The equations of quantum mechanics can also be brought, at least formally, into the form of Eq. (1) or (2); the intervention of complex quantities modifies the situation somewhat, in a way which we cannot discuss here.

Electromagnetic phenomena fall typically into the category of Eq. (1): each of the components of the electric field $\mathbf{E} \equiv (E_x, E_y, E_z)$ and of the magnetic field $\mathbf{H} \equiv (H_x, H_y, H_z)$ satisfies, in vacuum, Eq. (1), with $F = 0$; the connections between \mathbf{E} and \mathbf{H} are given by the Maxwell equations, which characterize completely the theory, and lead in vacuum to the result just

mentioned. When \mathbf{E} or \mathbf{H} does not vary with time, Eq. (1) reduces to Eq. (3), thus yielding electro- or magnetostatics.

The electromagnetic field, i.e., the vectors \mathbf{E} and \mathbf{H} , generated by a distribution of moving charges or currents confined within a limited volume has a part which becomes dominant at a large distance from that volume, because it decreases only with the inverse of that distance (instead of the inverse-square law of static fields); this part constitutes the *radiation* field, which is responsible for the transmission of energy and signals (the radiated energy is, of course, supplied by the mechanism which drives the generating charges or currents). This is easy to understand: the energy radiated through a large sphere around the source is proportional to the area of the sphere times the square of E ; it vanishes therefore with increasing radius for all but the radiative component, for which it stays constant: energy is actually removed from the source and radiated away to all distances. The study of radiation is a most important part of the theory, both macroscopically (telecommunications, radar) and microscopically (atoms, nuclei, elementary particles).

Relativity and quantum mechanics have extended and modified profoundly the classical picture presented so far. The very concepts of space and time change with special relativity: events which are simultaneous for an observer are not such when seen by another observer in uniform motion with respect to the first, because time and space are mixed together by the Lorentz transformations which relate the reference frames associated with the two observers. As a consequence, the laws of nature can retain their universal validity only if they are formulated in the same form by any such observer, i.e., if their form is not altered by a Lorentz transformation—technically speaking, if they are "Lorentz covariant." This requirement becomes a stringent dogma; it suffices to determine, with the help of group theory, the possible equations for any conceivable relativistic field theory; it is of invaluable help, when computations are made, in checking or correcting them.

The nonrelativistic Schrödinger equation for the wave function of a particle is, but for the appearance of complex quantities, of the type (2) described before: this is not acceptable in a relativistic world, because time and space are not treated alike. One needs either an equation which contains only second-order derivatives, or one with only first-order derivatives; for a free particle, this leads either to the Klein-Gordon equation, which is of type (1), or to the Dirac equation, which contains linearly only the first-order derivatives of the wave function, but has a mathematical structure which necessarily assigns special physical properties to the particles described by it. It was one of the greatest triumphs theoretical physics ever witnessed, to discover that such properties are actually displayed by all particles which obey the Dirac equation: spin, and the existence for each Dirac particle of a

corresponding *antiparticle*, i.e., a particle having the opposite mechanical and electrical properties.

The requirement of relativistic covariance has thus led to fundamental physical discoveries; for each particle obeying the Dirac equation, the corresponding antiparticle has been experimentally found in nature; electron and positron, proton and antiproton, neutron and antineutron, etc. What is more, the theory predicts that a particle-antiparticle pair can be created in a collision phenomenon, if sufficient energy is available, or can annihilate itself, giving away its energy in the form of electromagnetic radiation or other particles.

The classical theory allowed only for the electromagnetic radiation emitted by moving charges or currents; the creation or absorption of particles in collision phenomena, as well as the creation or annihilation of pairs, were outside its scope and possibilities. A new formulation of the theory was needed, which could account consistently for all such phenomena, handling situations in which particles can be created and destroyed in any numbers. The formalism devised for this purpose is that of quantum field theory.

The basic idea is to describe each type of particle by means of a field which is not any more an ordinary numerical function of space and time, but an "operator," i.e., a quantity which changes the number of particles existing in any given state of the system. If the field operator is known, one can then evaluate the probability of a given state (so many particles, with determined energies and momenta) changing into an equally determined, different state. If the particles do not interact among themselves or with other particles, no change is possible; if there is interaction, the field operator has a structure which can cause such transitions. The field equations appear to be essentially the same as those of the classical Maxwell, Klein-Gordon, Dirac theories, etc.; their structure is however fundamentally different, because they now must be equivalent to infinite sets of ordinary equations, which couple states with different and ever-increasing numbers of particles.

Fields which are associated with particles obeying Bose-Einstein statistics (of which any number can be found in any given state) have radically different mathematical properties from fields associated with particles obeying Fermi-Dirac statistics (of which at most one can be found in any given state); examples of the first are photons (the massless neutral quanta of the electromagnetic field), pions (massive particles, with or without electric charge, which are believed to be responsible for nuclear forces), etc.; examples of the second are electrons and positrons, protons and antiprotons, etc.

The passage from numerical fields to operator fields is called "second quantization"; quantum field theory deals with operator fields.

Striking successes have been met with this approach. From a quantitative point of view, they are confined mostly to electrodynamics,

where very small deviations from the values predicted by the non-quantized theory, which were observed in the measurement of the magnetic moment of the electron and in the so-called Lamb shift, were accounted for with amazing accuracy by quantum field theory. Qualitatively, the new conceptual framework has proved extremely useful in understanding elementary phenomena, especially with the help of the diagrams devised by R. P. Feynman, which give a simple intuitive picture of collision and radiation processes involving elementary particles. Very little has been achieved quantitatively, though, for theories other than electrodynamics, because of the tremendous mathematical difficulties which arise as soon as the simplest approximation techniques are not applicable because the interaction is too strong; nevertheless, these ideas have proved greatly helpful in many ways, in combination with general principles of symmetry, Lorentz invariance and causality.

A beautiful consequence of this conception, which assumes that particles are the quanta of a field (as photons were recognized by Einstein to be the quanta of the electromagnetic field) was the discovery of H. Yukawa, that whenever such quanta have a mass different from zero, the force they create between two bodies which interact by exchanging such quanta with each other must be an exponentially decreasing function of distance; this force can become of a coulombian type only if the mass of the quanta vanishes. Thus, the Coulomb force can be explained as due to the exchange of photons among electric charges, the nuclear forces (which have typically short ranges) as due to the exchange of massive particles among nucleons. Exchanges of this nature are not observable in the laboratory, because this runs against Heisenberg's indeterminacy principle; if enough energy is supplied, however, such quanta can actually break loose and do appear as the particles created in collision processes.

The mathematical difficulties encountered in quantum field theory are many, and there is as yet lack of agreement as to the best way to circumvent some of them. Besides mathematical complexity, which prevents all but the simplest calculations, there are many unsolved problems of mathematical rigor and apparent inconsistencies which can be removed only by delicate analyses. Typical of the latter is the fact that unsophisticated calculations give infinite values for masses and charges of interacting particles, and a painstaking analysis is required to retrieve from them the significant physical values; this is the so-called renormalization procedure, which copes with infinities which partly are already present in the classical theory (such as the infinite electromagnetic contribution to the mass of a point-like charged particle, when computed from Maxwell's equations) and partly originate from the new formalism (which permits, for instance, pair creation).

It is not yet certain whether such difficulties are due to the lack of adequate mathematical techniques or are the expression of a fundamental

inadequacy of the theory to describe ultimate laws of nature. For this reason, while, on the one hand, the attention of some theoreticians has been directed to perfecting the mathematical foundations of quantum field theory (giving rise to axiomatic field theory and to more rigorous methods of obtaining and studying the quantum field equations, etc.), on the other hand, most physicists have been trying new avenues, such as the S-matrix theory, dispersion relations, the so-called Regge poles, etc.; these approaches have certainly led to very useful results, but they leave altogether at least as many doubts as hopes.

Whatever may be the future prospects of field theory as the correct means for describing the fundamental laws of nature, its tremendous usefulness in providing a conceptual framework, in inspiring new ideas, and in suggesting computational techniques has been overwhelmingly demonstrated in the last decades. It has now found a new, very fertile ground of application in the study of systems containing a very large number of particles, where it has already provided a reasonably good quantitative understanding of superconductivity and superfluidity, and promises many other results of interest in the study of solids and liquids.

FISSION*

Nuclear fission is the breakup of a heavy nucleus, such as that of uranium, into two medium-weight nuclei, with the release of a considerable quantity of energy. Also produced are a few neutrons, some gamma rays, and a number of beta-particles (electrons) from the radioactive decay of the two fragments. Fission occurs spontaneously in some cases, or may be induced by bombardment of the fissionable material with neutrons, protons, or other particles.

Discovery of Fission. Although fission was not discovered until 1939, it had been realized, ever since Einstein published his theory of relativity in 1905, that there was a theoretical possibility of releasing tremendous energy from matter.

Fission is now known to have been first produced by Enrico Fermi and his co-workers in 1934, when they irradiated many elements, including uranium, with the newly discovered neutrons. They found a number of different β -activities to be produced from uranium, but believed that these were due to neutron capture. Later radiochemical work indicated that some of the new activities were from elements chemically similar to the much lighter elements Ba, La, etc.

Fission remained unrecognized until O. Hahn and F. Strassmann, German radiochemists,

showed by very careful work that these products were not merely chemically similar to lighter elements, but *were* lighter elements. They published their startling results in the January 6, 1939 issue of *Naturwissenschaften*. On January 16, Lise Meitner and O. Frisch sent in to *Nature* (from Stockholm and Copenhagen) a paper in which they named the new process "fission," predicted that the fragments should have large kinetic energies, and explained the process in terms of a liquid-drop model. On the same date, Frisch sent in to *Nature* another paper in which he reported that he had observed the large electrical pulses from fission fragments in an ionization chamber.

Niels Bohr in the meantime had taken the news of the discovery of fission, and the prediction of large energies, to a conference on physics in Washington, D. C. During the conference physicists in a number of laboratories independently verified the tremendous kinetic energies of fission fragments, unaware as yet of Frisch's results.

During the months following the discovery of fission, there was feverish activity in laboratories around the world. It was soon discovered that neutrons were being produced by fission, and that almost all of the fission of U was taking place in the relatively rare isotope, U^{235} . In that same year (1939), Bohr and Wheeler published their theory of fission, based on the liquid-drop model, which is still basic to modern fission theory.

Development of Atomic Energy. On the date of publication of the Bohr-Wheeler paper, September 1, 1939, Germany invaded Poland, the Second World War was underway, and fission suddenly had a new importance. It was realized by many that a chain reaction was possible for fission, with the neutrons from each fission producing more fissions, resulting in the release of very large amounts of energy.

The fission process results in the conversion of 0.09 per cent of the mass of the original nucleus into kinetic energy. This amounts to about 200 MeV per fission, or 3.20×10^{-11} joules. The fission of 1 kilogram of U^{235} thus releases a total energy equal to 8.21×10^{14} joules, or 2.28 $\times 10^7$ kilowatt-hours. This is roughly equal to the daily output of Hoover Dam, and very much greater than the energy released in chemical reactions. One kg of U^{235} is equivalent in energy release to the burning of 3.45×10^6 kg of coal (C) by 9.20×10^6 kg of oxygen. This chemical process releases 7.2×10^{11} of the mass as heat energy, more than 10 million times smaller than for fission.

The fission of 1 kg of U^{235} is also equivalent in energy released to the detonation of 19.6×10^3 kg (19.6 kilotons) of high explosive. A kiloton, 1000 metric tons, is conventionally taken to be equivalent to 10^{12} calories, or 4.186×10^{12} joules; a megaton is 1000 times larger.

Thus it was known to many people in 1939 that it might well be possible to produce the destructive effect of many thousands of tons of high explosive with a single bomb containing a

* Work performed under the auspices of the U.S. Atomic Energy Commission.

relatively small amount of fissionable material. It seemed probable that Germany would press ahead with this development. Aware of this danger, scientists in the rest of the world largely ceased publishing fission results by 1940.

Work on fission was continued quietly at an increasing rate. In June 1942, the Manhattan Project (under U.S. Army direction) was set underway in the United States, with the objective of producing nuclear weapons, if possible. The first chain reaction was produced on December 2, 1942, under the direction of Enrico Fermi, who had arrived from Fascist Italy in January 1939. Fermi and his co-workers had piled up blocks of ordinary uranium and extra-pure graphite (carbon) to produce a nuclear reactor, under Stagg Field Stadium of the University of Chicago. The carbon was used to slow down fission neutrons and thus increase the likelihood of fission. Cadmium rods inserted in the reactor (at that time called a "pile") were used to control the chain reaction by capturing a certain fraction of the neutrons.

Thus, by December 1942, a fission chain reaction had been achieved. In the following years, research vital to the Manhattan Project was carried on at many laboratories. In order to produce the fissionable material for nuclear weapons, two tremendous industrial plants were set up beginning in 1943, at Oak Ridge, Tennessee, and Hanford, Washington.

The Oak Ridge plant was for the purpose of separating the more fissionable isotope, U^{235} , from the much more common isotope, U^{238} , which accounted for 99.3 per cent of the mass of ordinary uranium metal. The most successful separation process, which is still in use at Oak Ridge, was that of gaseous diffusion. Uranium in the form of a gas, uranium hexafluoride, is passed through a long series of porous barriers. The lighter isotope U^{235} can diffuse more readily than U^{238} , and the result of the process is enriched uranium, the U^{235} content having been increased from 1 part in 140 to perhaps 95 per cent.

The Hanford plant consists of giant nuclear reactors to produce a new element, plutonium, from ordinary uranium by neutron capture. It was thought, and eventually proved, that plutonium should be fissionable by slow neutrons in the same way as U^{235} . Capture of a neutron by U^{238} produces the heavier isotope U^{239} , which then decays by beta-emission to the new element Np^{239} (neptunium), and then by another beta-decay to Pu^{239} .

The work of designing and building nuclear weapons was carried out at a laboratory set up at Los Alamos, New Mexico. This laboratory, under the direction of J. Robert Oppenheimer, began its work in early 1943. Before the end of the war, a good fraction of the world's most eminent nuclear physicists had come to work at Los Alamos, including Bohr, Fermi, Frisch, and many British scientists.

One of their most basic problems was to find a way to assemble the fissionable components of a

weapon rapidly enough to produce a powerful chain reaction, lasting less than one μ sec. The individual masses of enriched uranium or plutonium had to be of such a size and shape as not to be capable of a chain reaction; i.e., they had to be of less than critical mass. If these pieces were not assembled at sufficient speed, the result would be only a minor explosion, or perhaps the melting of the device. Two approaches were tried. One involved firing one piece of fissionable material at another in a short "gun." The other was the implosion method, in which the fissionable material is assembled into a highly compressed mass by the explosion of a surrounding spherical shell of high explosive.

Both methods of achieving a nuclear explosion were ultimately successful, but it was not known whether either method would work until July 16, 1945, when the first nuclear weapon ("atomic bomb") was set off in a desert area near Alamogordo, New Mexico. On August 6 a weapon was exploded over Hiroshima, Japan, and on August 9 another was detonated over Nagasaki. Each weapon had a yield equivalent to about 20 kilotons of high explosive and caused tremendous destruction. On August 10, the Japanese first offered to surrender, and accepted Allied terms on August 15; the mobilization of the massive United States invasion force was called off. Germany, which had surrendered on April 8, 1945, was found to have made little progress toward nuclear weapons during the war.

Following the end of the war, the work on nuclear weapons and nuclear power in the United States were placed under the newly created (1946) Atomic Energy Commission. Similar agencies have since been set up in many countries. On August 29, 1949, the U.S.S.R. detonated its first nuclear device. During the next several years, enormous production plants for U^{235} were built at Paducah, Kentucky, and Portsmouth, Ohio, as well as facilities for producing Pu^{239} and hydrogen isotopes on the Savannah River in South Carolina. On November 1, 1952, the Los Alamos Scientific Laboratory exploded the first thermonuclear device ("hydrogen bomb"), with a yield equivalent to many megatons of high explosive. Such a weapon uses nuclear fission to trigger nuclear fusion, in which light elements (such as the various isotopes of hydrogen) are combined at exceedingly high temperature to give heavier nuclei, with considerable release of energy. On August 12, 1953, the Russians set off their first thermonuclear weapon. In the years since then, the British, French, and Chinese have all developed their own nuclear weapons.

Nuclear reactors and nuclear power have been developed extensively since the war, in many countries. Nuclear-powered submarines, aircraft carriers, and other vessels have revolutionized naval strategy. Nuclear-propelled rockets (the "Rover" program at Los Alamos) will probably soon be used in space exploration. The use of nuclear explosives for earth-moving and other engineering purposes has been an extensive project ("Plowshare") of the Lawrence Radiation

Laboratory at Livermore. Nuclear power plants are rapidly becoming more widespread, and more economical.

Chain Reactions. The basic feature which makes both nuclear reactors and nuclear weapons possible is the "chain reaction," in which each fission produces another fission, or several, by means of the several neutrons emitted from fission. If there is not enough fissionable material, or it is not arranged compactly enough, no chain reaction will be possible. The fission neutrons emitted in such a situation will have too great a chance of escaping from the fissionable material, or of being absorbed in non-fissionable material, to continue the chain of fissions should one fission occur.

There is thus a "critical mass," or minimum amount of fissionable material, necessary for a chain reaction in any given arrangement. For a spherical mass of metal in air, the critical mass of highly enriched (94 per cent) U^{235} , for instance, is 52 kg; the critical mass for U^{233} or Pu^{239} metal is lower, about 16 kg. The critical mass can be lowered by mixing fissionable material with graphite or other material as a "moderator" to slow down the neutrons, or by surrounding the fissionable material with a reflector to scatter neutrons back.

The smallest critical masses are achieved by water (or heavy water) solutions of fissionable material, since H and D are most effective in slowing down neutrons. The "Water-Boiler" thermal reactor at Los Alamos operates ordinarily with about 800 grams of enriched uranium in water solution, and has gone critical with less than 600 grams.

The energy of the neutrons producing most of the fissions in a reactor determines whether it is called "fast," "intermediate," or "thermal." Fast reactors use neutrons only slightly slowed down from the 2-MeV average energy with which they are emitted. Thermal reactors use neutrons slowed down, by collision with moderator atoms, almost to the velocities corresponding to thermal motion at the temperature of the reactor. At 294 K, about room temperature, the most probable velocity is 2200 meters/sec., which corresponds to a neutron energy of 0.0253 eV. Intermediate reactors use partially slowed down neutrons, with less than 100-keV energy.

In order for a chain reaction to continue, it is necessary that each fission produce, on the average, at least one more fission. The average number of fissions produced by the neutrons from one fission is called k , the criticality factor or multiplication constant. If k is less than 1.0 (the critical value), a chain reaction, even if begun with many fissions, will soon die out.

A reactor must have $k = 1.0$ during normal, steady, operation, and must have k greater than 1.0 during the start-up operation. These changes in criticality factor can be brought about by introducing or removing from the reactor control rods made of neutron-absorbing elements, such as cadmium or boron.

This regulation of reactor power is made much

easier by the phenomenon of delayed neutrons, which are emitted from some fission products for a few seconds after the fission. In the case of thermal-neutron fission of U^{235} , 0.65 per cent of the neutrons produced (0.0158 out of 2.42 neutrons per fission) are delayed in this way. Only if k were increased above 1.0065 in this case could the reactor power increase rapidly, as each fission would then, on the average, produce one more fission promptly. Reactors are of course designed to avoid this "prompt critical" condition, as this could lead to overheating and destruction of the reactor. In any case, reactors cannot possibly achieve the high values of the criticality factor needed for a nuclear explosion.

The Fission Process. The fission of a nucleus can be understood on the basis of the liquid-drop model, which was first discussed by Meitner and Frisch and later greatly extended by Bohr and Wheeler. This model explains many features of fission, but others are still not fully understood, and the complete theory of fission is still awaited.

On the basis of this model, the nucleus is assumed to be similar to a uniformly charged drop of incompressible liquid. It will then be normally spherical, kept in this shape of minimum energy by the effect of surface tension. However, the individual parts of the positive charge, actually protons, tend to repel each other and to lessen the effective surface tension. It has been calculated that the two effects will cancel each other out for a value of Z^2/A equal to about 45 (Z is the atomic number or the number of protons; A is the mass number or total number of nucleons in the nucleus). The ratio of Z^2/A to this critical value is called the fissionability parameter x .

For a fissionability parameter equal to 1.0, the nucleus should have no effective surface tension and no stability against distortion, so that it should promptly elongate to a point where the coulomb (electrostatic) forces can blow it apart. Such a nucleus would have no "fission barrier" and could not exist long. Known nuclides have lower values of the fissionability parameter; for U^{235} the value of x is about 0.8. For such nuclei, it takes 5 or 6 MeV of energy to deform the nucleus to the point where coulomb forces can cause fission. However, such a fission barrier may be overcome by the capture of a neutron, which adds an excitation energy of 5 or 6 MeV.

For the even- Z , odd- N nuclides U^{233} , U^{235} , and Pu^{239} (N is the number of neutrons in the nucleus), fission can be induced by the capture of even a low-energy neutron. Even-even target nuclides require more energy, so that U^{238} is very unlikely to fission upon capture of a thermal neutron, but needs about 1 MeV additional neutron energy to overcome the fission barrier. Even-even compound nuclei (i.e., after neutron capture) are evidently more likely to undergo fission. Even-even nuclei are also much more likely to undergo spontaneous fission, in which an occasional nucleus manages to overcome the fission barrier without any added energy. Fission may also be induced by gamma

rays of energy equal to the fission barrier or by energetic particles of many kinds such as protons or alpha particles.

The probability that particles passing through a target of fissionable material will induce fission is measured by the fission cross section. The "cross section" is the effective area of a nucleus for a given process. For a thin target of thickness t / cm having n nuclei per cubic centimeter, each with fission cross section σ cm², the probability that a particle passing through the target will induce a fission is $n\sigma t$.

Figure 1 shows the fission cross section for 11 fissionable nuclei, as a function of the energy (in MeV) of the neutron inducing fission. For those nuclides (U^{233} , U^{235} , Pu^{239}) which lead to even-even compound nuclei, the cross sections are very high for low-energy neutrons; these are "fissile" nuclides. For the other target nuclides, the fission cross section is extremely small until the neutrons have energy in excess of a threshold energy. All the cross sections may be seen to increase noticeably at about 7 MeV. This increase is due to the added possibility of fission following low-energy neutron emission, which becomes energetically possible here.

The energy released when fission takes place amounts to about 200 MeV. This is the difference in mass between a heavy fissionable nucleus and the two medium-weight nuclei, plus neutrons, into which it breaks up. This energy release of 200 MeV amounts to 21.3 per cent of the mass of a single proton or neutron. Most of the energy

appears in the form of kinetic energy of the two fission fragments, which are sent flying apart with an average total of 167 MeV in the case of thermal fission of U^{235} .

The two fragments share the kinetic energy in the inverse ratio of their masses, since they have equal and opposite momenta. The mass division is usually asymmetrical, as may be seen in Fig. 2. The probability that neutron fission of U^{235} will produce two given fragments of nearly equal mass (symmetrical fission) is about 600 times lower than that of the most probable case of asymmetrical division into light and heavy fragments. The initial fragments (before neutron emission) in this case have masses averaging 96 and 140 mass units. The lighter fragment has on the average about 99 MeV of kinetic energy, and the heavy fragment about 68 MeV. These energies correspond to initial velocities of 1.4 and 1.0×10^9 cm/sec, or 4.7 and 3.2 per cent of the speed of light, respectively. The total fragment energy is rather closely given, on the average, by $0.121 Z^2/A^{1/3}$ MeV.

Such fragment energies are due to the Coulomb interaction between the two fragments, and would be expected on the basis of any fission theory. The asymmetrical mass division, however, would not be predicted by liquid-drop theory and has so far resisted detailed explanation. The liquid-drop model would, in its simplest form, predict primarily symmetrical fission, which is rarely observed.

The fragments, as we have seen, carry away

FIG. 1. Dependence of fission cross section (a "barn" is 10^{-24} cm²) on inducing neutron energy (in MeV) for 11 different fissionable nuclei (reprinted with permission from R. L. Henkel, "Fission by Fast Neutrons," in J. B. Marion and J. L. Fowler, Eds., "Fast Neutron Physics, Part II," New York, Interscience Publishers, 1963).

FIG. 2. Dependence of neutron yield on initial fragment mass for thermal-neutron fission of U^{235} . Average numbers of neutrons emitted by light and heavy fragments are given the symbols ν_L and ν_H , the total from both fragments is ν . Standard deviations are indicated by dotted lines. Also shown are the initial and final mass yields [reprinted from J. Terrell, *Phys. Rev.*, **127**, 880-904 (1962)].

most of the 200-MeV energy release in the form of kinetic energy. The rest of the energy is released in the form of neutron energy, gamma rays, and beta decay. The prompt neutrons, which are emitted within 10^{-11} sec. following fission, will be discussed below. The fission fragments are strong sources of prompt gamma rays, emitting about 8 within a microsecond or less following fission. The gamma rays have a broad spectrum of energies, up to as much as 7 MeV, but they average about 1 MeV apiece, so that the total energy emitted in prompt gamma rays is about 8 MeV. This is more than simple theories would predict.

Immediately after the emission of neutrons and prompt gamma rays, the fragments (now called "fission products") begin the process of beta decay, which ultimately accounts for perhaps 22 MeV of fission-energy release. The fission products have neutron-to-proton ratios which are nearly the same as that of the heavy nucleus from which they were formed (about 1.55). This is too many neutrons for stability in the fission-product mass region, where nonradioactive nuclei have neutron-proton ratios in the range 1.3 to 1.4. Since there is thus energy to be released by changing neutrons to protons, the result is a long sequence of beta decays averaging 3 or 4 for each fission product. Each beta decay results in the emission of a negative electron, a neutrino, and usually gamma rays, and an increase of the charge of the nucleus by one unit. The neutrinos ultimately carry away about 10 MeV of the energy released, and for all

practical purposes, this energy is not detectable and is never seen again. The fission products are intensely radioactive immediately after fission, as the beta decays having the shortest half-life are completed, and gradually become less radioactive with the passage of time.

For a small fraction of the fission products it is energetically possible for a neutron to be emitted at some stage in the chain of beta decays. These delayed neutrons, amounting on the average to 0.0158 per thermal-neutron fission of U^{235} , are very useful in stabilizing the operation of nuclear reactors, as mentioned above. Because they are emitted immediately following beta decays, they appear to follow the same radioactive decay curves as some of the beta decays, and have varying half-lives, of the order of seconds.

In rarer cases - about one fission out of 400 - an alpha particle (He^4) is emitted during the fission process, in addition to the two fragments. This process is usually called ternary fission, as distinguished from the usual binary fission. Because of the high energy (averaging 15 MeV) and direction (roughly perpendicular to fragment motion) of the alpha particle, it is probably formed at the same time as the two heavier fragments, and between them. In still rarer cases, a lighter charged particle such as a nucleus of tritium (H^3) is seen. There seems even to be evidence that, in perhaps one fission out of 100,000, three fragments of roughly equal mass are formed.

In the vast majority of fissions, however, two fragments and several neutrons are the result. For low-energy fission it is clear that most, or perhaps all, of the neutrons are emitted by the fragments. The average number of neutrons per fission ($\bar{\nu}$) ranges from 2.0 to 4.0 for various nuclides. Fission at high energies, such as that induced by 100-MeV alpha particles, produces many more neutrons, most of which were emitted before fission.

In the typical case of thermal-neutron fission of U^{235} , $\bar{\nu}$ is 2.42. For individual fissions the number ν can vary from zero to 5 or 6, the standard deviation from the average being ± 1.10 . The neutrons in this case have an average energy of 2.0 MeV, and the energy spectrum for U^{235} is often described by the Watt spectrum,

$$N(E) = -0.48394e^{-E} \sinh(\sqrt{2E})$$

Here $N(E)$ is the number of neutrons per unit energy E , in MeV, and the normalizing constant is chosen to give an integral of 1.0 over the entire spectrum. Another, more general, representation of the neutron spectrum is the Maxwellian distribution,

$$N(E) = (2/\sqrt{\pi T^3})^{1/2} E e^{-E/T}$$

in which T is a parameter equal to two-thirds of the average energy \bar{E} . Such a spectrum is predicted from nuclear temperature theory.

Of the roughly 2-MeV average energy per neutron, about 0.75 MeV is contributed by the motion of the emitting fragments. There is evidence that the average neutron energy increases with increasing number of neutrons. This would be expected from considerations of nuclear temperature, which lead to the relation $\bar{E} = 0.75 + 0.65 \sqrt{\bar{\nu} + 1}$, in MeV, in agreement with experimental data.

The total kinetic energy carried away by the typical 2 or 3 neutrons per fission is thus about 5 MeV, of which 2 MeV is taken from fragment energy. The fragments after neutron emission thus have a total energy reduced (in the case of U^{235}) from 167 to 165 MeV, and lower mass numbers.

The final fragment masses may be determined by radiochemical data on fission products. The final mass yields for U^{235} are shown in Fig. 2, as crosses. The initial mass yields may be determined from simultaneous measurement of the velocities of the two fragments and are also shown in the Figure. The differences between initial and final mass yields are accounted for by emission of neutrons and may be used to determine the numbers of neutrons. The average numbers of neutrons emitted by individual fragments are shown (ν_L and ν_H) as functions of fragment mass; the total $\nu (= \nu_L + \nu_H)$ is also shown.

As may be seen in Fig. 2, the average number of neutrons emitted by a fission fragment depends strongly on the fragment mass; it is near zero for the lightest of the light fragments, and also for

the lightest of the heavy fragments, and rises to high values elsewhere. Thus the two fragments from a fission will usually emit quite different numbers of neutrons, which implies quite different initial excitation energies. This phenomenon came as quite a surprise when it was first reported by Fraser and Milton in 1954. It has since been found to be a common and perhaps universal feature of fission.

It seems now that this "sawtooth" dependence of neutron number on fragment mass may be understood on the basis of varying stiffness of the fragments against deformation. The fragments having "magic" numbers of neutrons or protons would be expected to be stiff and to be exceptionally resistant to deformation and the consequent excitation. The magic number of neutrons, $N = 50$, will occur for fragments in the vicinity of mass 82, at the lower boundary of the light fragment peak. Similarly, two magic numbers ($Z = 50$ and $N = 82$) occur at the lower edge of the heavy fragment peak, near mass 130. The low neutron yields seen at these magic-number positions may be quantitatively explained on the basis of the effects of magic numbers on the deformation parameters. It is hoped that this new "fragment deformation" theory will be able to account quantitatively for the little-understood spectrum of fragment masses, since the mass yields and neutron yields tend to vanish near the same magic numbers.

FLIGHT PROPULSION FUNDAMENTALS

Propulsion is not a science in itself, and has no unique basic principles of its own. The fundamentals of propulsion really are selected from the basic laws of MECHANICS, THERMODYNAMICS, and CHEMISTRY; certain special types of propulsion require also some principles of ELECTRICITY or NUCLEONICS.

Propulsion is defined here as the act of changing the natural state of motion of a vehicle flying in air or in space. Thus a propulsion mechanism applies a force to a flying body and so changes the momentum of the body, or, in the case of maintaining steady, level equilibrium flight, the force of propulsion overcomes or equals the atmospheric drag. To propel a vehicle, it is necessary to accelerate another mass (usually a gaseous fluid) in the opposite direction. Hence, not only Newton's basic laws of motion, but also the conservation of momentum (change of momentum of vehicle equals change of momentum of ejected high-velocity masses) and the perfect gas laws are important here (see CONSERVATION LAWS AND SYMMETRY AND IMPULSE AND MOMENTUM).

The acceleration of a *gaseous working fluid* (often called propellant) to high exhaust velocities requires the supply and expenditure of energy. Thus, it is possible to classify flight propulsion systems according to their energy sources and the types of propellants (see Table 1). The device which creates and/or converts the energy into the form which is useful for propulsion is called an *engine*. It is the purpose of this section to summarize some of the most important propulsion relationships and to describe briefly the principal engine types.

Fundamental Relations. Assume an ideal engine inside of which the fluid receives energy and is heated and accelerated as shown schematically

in Fig. 1. The acceleration of a mass flow of air or fluid \dot{m}_a from an initial velocity v_0 (which equals the forward flight velocity of the vehicle) to the jet velocity at the exit v_e will result in a net thrust F , which is equal to the mass flow rate multiplied by the velocity increment. Additional

FIG. 1. Simple engine.

terms are added to this momentum relation in order to correct for the additional mass flow rate of the fuel or propellant (\dot{m}_p) (the fuel is carried in the vehicle) and for any difference in static pressure of the jet exit of the engine (p_e) and the atmospheric or ambient pressure p_0 .

$$F = \dot{m}_a(v_e - v_0) + \dot{m}_p v_e + A_e(p_e - p_0)$$

The last term in this equation is called the pressure thrust; it is positive if $p_e > p_0$ (which occurs when there is incomplete expansion of the gases in the engine exit nozzle) or negative if $p_e < p_0$ (which occurs when there is overexpansion in the engine exit nozzle). For a rocket engine, the air mass flow $\dot{m}_a = 0$, and the thrust is equal to the last two terms of the equation only. In the case of a propeller engine, there are really two different air flows, and the first term in the above equation is split into two separate terms: one flow which crosses the plane of the propeller and is accelerated by the propeller blades and a second smaller airflow which goes through the engine to furnish oxygen for combustion. In the case of a nuclear

TABLE 1. ENERGY SOURCES AND WORKING FLUID FOR SEVERAL FLIGHT PROPULSION DEVICES

Type of Propellant	Type of Energy Source		
	Chemical	Nuclear	Solar
Surrounding medium used as working fluid	Aircraft piston engine with propeller	Nuclear turbojet Nuclear ramjet Nuclear submarine with propeller	--
Surrounding medium plus stored propellant or fuel	Turbojet Ramjet Blasted rocket	Nuclear turbojet with afterburning of chemical fuel	--
Propellant stored within vehicle	Liquid and/or solid propellant rocket Chemical battery with electric propulsion	Nuclear H_2 fission rocket Nuclear reactor power source with electrical propulsion	Solar heated hydrogen rocket
No propellant expelled	--	Future photon rocket	Solar sail

reactor energy source, $\dot{m}_p = 0$ and the second term can be omitted. In a vacuum $p_0 = 0$.

Consider a winged vehicle in equilibrium rectilinear flight in a two-dimensional (fixed plane) trajectory; assume all control forces, lateral forces and turning moments to be zero and the flight direction to be the same as the thrust direction. In the direction of the flight, the instantaneous vehicle mass m_v times the vehicle acceleration dv/dt has to equal the sum of all the forces, namely a component of the thrust F , the aerodynamic drag D , and a component of the gravitational attraction or the weight $m_v g$. The angles are as defined in Fig. 2.

$$m_v dv/dt = F - D - m_v g \sin \theta \quad (2)$$

The vehicle mass m_v multiplied by the acceleration in a direction perpendicular to the flight

FIG. 2 Simple free body diagram of flying vehicle.

path ($v d\theta/dt$) must equal the sum of all forces perpendicular to the flight direction; here, the lift force L must be considered.

$$m_v v \frac{d\theta}{dt} = L - m_v g \cos \theta \quad (3)$$

The solution to these two equations results in the determination of a two-dimensional trajectory, maximum flight velocity, range, and other flight performance parameters. The actual solution is three-dimensional, and must usually be a numerical integration since m_v decreases with time, L and D vary with speed and altitude, and the direction of thrust is not the same as the flight direction; also, both the flight angle and the angle of attack are usually changing. For the case of a linear, simplified horizontal equilibrium flight, $\theta = 0$, $dv/dt = 0$, and thus Eq. (2) reduces to $F = D$. The vehicle mass m_v consists of the vehicle dry mass or final vehicle mass after expenditure of all propellant $(m_v)_f$ plus the propellant or fuel mass m_p . For steady fuel flow, $m_p = \dot{m}_p t$. For the case of gravity-free flight in a vacuum (true space environment), Eq. (1) can be rewritten for a rocket:

$$\frac{dv}{dt} = \frac{F}{m_v} = \frac{\dot{m}_p v_e}{(m_v)_f + m_p t}$$

Integration gives

$$v_v = v_e \ln \frac{m_v}{m_v - m_p} = v_e \ln \frac{(m_v)_f}{(m_v)_f - m_p}$$

Thus the maximum velocity attained by a rocket-

space vehicle operating in a gravitationless vacuum is equal to the product of the average effective rocket exhaust velocity v_e and a logarithmic function of the initial vehicle mass $(m_v)_f = (m_v)_f + m_p$ (fully fueled vehicle) at start of the engine operation, divided by the final vehicle mass (with all the fuel expended) $(m_v)_f$ at the end of engine operation. This velocity v_v will be large when v_e is large, i.e., high energy is available from the propellant or the engine and when $(m_v)_f$ is small, i.e., when the dry mass of the vehicle (dry engine mass, tanks, payload, or structure) is small and no unnecessary mass is designed into the vehicle. This means that m_p is large and the initial vehicle mass $(m_v)_f$ consists largely of propellant.

The *specific impulse* of an engine can be defined as the thrust force obtained from a unit propellant weight flow.

$$I_s = \frac{F}{\dot{w}} = \frac{F}{mg} \quad (\text{kg force/kg mass per second})$$

Since the propellant usually refers to the fuel stored in the vehicle and not to the air flow, the values of I_s for air-breathing engines are generally very high.

The *specific fuel consumption* (sfc) is usually expressed as the fuel flow rate (pounds per hour) per engine shaft brake horsepower. Both of these parameters are an indication of the quality of design and operation of an engine; a high value of I_s or a low value of (sfc) indicates efficient use of propellant or fuel.

Some of the most significant types of engines are described briefly in the remainder of this section.

Rocket Engines. These engines use both a fuel and oxidizing propellant and both are stored within the flying vehicle, making it independent from its surrounding fluid. Thus a rocket can operate in space, air, or under water. The supersonic nozzle jet exit velocity v_e of a rocket using ideal gas laws can be derived to be

$$v_e = \sqrt{\frac{2gkR}{(k-1)M} \frac{T}{p_c}} \left[1 - \left(\frac{p_e}{p_c} \right)^{(k-1)/k} \right]$$

where

v_e	nozzle exit velocity
g	gravitational constant
k	ratio of specific heats of gas
R	universal gas constant
M	molecular weight of hot gas
T	absolute combustion temperature
p_c	nozzle exit gas pressure
p_e	combustion chamber pressure.

The exhaust velocity (or the specific impulse which is $I_s = v_e/g$) increases as the molecular weight M is decreased or as the combustion temperature T is increased. Because of the pressure ratio effect, there is actually a slight (10 to 20 per cent) increase in specific impulse as the altitude is increased (lower ambient pressure) or as chamber pressure is increased. Air-breathing

engines, in comparison, lose specific impulse with altitude. Values of v_e or I_s calculated for a given propellant and engine from thermochemical and thermodynamic data are usually very close to actual performance (usually within 5 to 10 per cent), because rocket combustion efficiencies are high and nozzle losses are usually low. Schematic diagrams of several liquid and solid propellant systems are shown in Figs. 3 to 7, and some important applications are shown in Table 2.

In *liquid propellant rocket engines* the propellants are fed under pressure from tanks in the vehicle into a thrust chamber where they are injected, mixed, and burned at high pressures and very high temperatures to form the gaseous reaction products, which in turn, are accelerated in a nozzle and ejected at high velocities. The feed system for transferring the propellants into the thrust chamber includes valves and controls.

The principal components of a *thrust chamber* (Figs. 3 and 4) are the *nozzle*, the *chamber*, and the *injector*. An injector introduces and meters the flow of the liquid propellants and also atomizes and mixes them in the correct proportions in such a manner that they can be readily vaporized and burned. In the combustion chamber, the burning of the liquid propellant takes place at high pressure, usually between 5 and 150 atmospheres.

The *gas pressure feed system* (Fig. 3) offers one of the simplest and most common means of transferring propellants by displacing them with a high-pressure gas which is fed into the tanks under a regulated pressure. In a *turbopump feed system*, the propellant is pressurized by means of pumps driven by one or more turbines (Fig. 4) which derive their power from the expansion of hot gases. A separate gas generator ordinarily produces these gases in the required quantities

and at a temperature which will not hurt the turbine buckets (1200 to 2000°F).

Liquid propellants. A *bipropellant rocket unit* has two separate propellants, a fuel and an oxidizer

TABLE 2. TYPICAL DATA FOR VARIOUS ROCKET ENGINES

Type	Typical Range of Thrusts (lbs)	Typical Range of Duration	Application
High thrust liquid propellant rocket	1,000,000 to 4,000,000 for each engine with several engines in a cluster	1 to 5 min	Booster and sustainer stages of large missiles and space vehicles
Large solid propellant rocket	5,000 to 3,000,000	1 to 60 sec	Large and small missiles (surface to surface, surface to air, air to air, air to surface)
Prepackage storable liquid propellant	100 to 100,000	1 to 60 sec	Special applications of small missiles, lunar landing and takeoff
Jet assisted takeoff (solid propellant)	200 to 10,000	5 to 30 sec	Assist takeoff of airplanes
Space vehicle attitude control	1 to 150	0.01 to 10 sec/cycle; accumulate up to an hour	Control position, angle and orientation of spacecraft

FIG. 4. Simplified schematic diagram of liquid propellant rocket engine with turbopump feed system and regeneratively cooled thrust chamber (reproduced by permission from McGraw-Hill Encyclopedia of Science and Technology, Vol. II, New York, McGraw-Hill Book Co.)

(such as kerosene and liquid oxygen), which are not mixed until they come in contact with each

other in the combustion chamber. Most liquid propellant rockets have been of this bipropellant type. A *monopropellant* contains oxidizing agent and combustible matter in a single substance. It can be a mixture of compounds, such as hydrogen peroxide with liquid alcohol, or it may be a homogeneous chemical agent, such as nitromethane. Certain types of liquid fuels and oxidizers are self-igniting and start burning when they come in contact with each other. Other types of propellants, for example, oxygen and alcohol, are not spontaneously ignitable, but require an igniter to furnish thermal energy for starting their combustion reaction. Typical values for liquid and solid propellants are given in Table 3.

Solid Propellants. In a *solid propellant rocket engine* all the propellant is contained within the combustion chamber. The hardware includes, in addition to the combustion chamber nozzle, an igniter and provisions for mounting the rocket (Figs. 6 and 7). Solid propellants themselves usually have a plastic, cakelike appearance (specific gravity is approximately 1.6) and burn at high pressure (10 to 150 atmospheres) on their exposed surfaces to form hot exhaust gases which are ejected through the nozzle. The physical mass or body of the propellant is called the *grain*. In some rockets, there is more than one grain inside the same combustion chamber.

The solid propellant grain contains all the material necessary for sustaining combustion. It can be a mixture of several chemicals, e.g., a mixture of ammonium perchlorate in a matrix of organic polymeric fuel such as rubber. Or it can be a homogeneous charge of special oxidizing organic chemicals, such as nitrocellulose or nitroglycerine. Once the propellant is ignited,

the grain burns smoothly on all of its exposed surfaces in a direction normal to the burning surface.

Compared to liquid propellant, the solid propellant requires no pump or pressurization for the fuel tank, and hence is mechanically simpler. The combustion chamber with solid propellant is larger, especially for large rockets, and is frequently operated at higher pressure than for a liquid engine. Solid rockets are simpler, more storable, and are usually more immediately ready for use, but are generally lower in performance when compared to liquid propellant units.

Most solid propellant grains are somewhat sensitive to variations in the ambient temperature and have a tendency to become soft on very hot days or brittle on very cold days; for certain propellants, therefore, it is necessary to restrict the temperature range over which they may operate. If the propellant should crack from too great a temperature variation (which induces thermal stresses) or from rough handling, additional burning surfaces would be created in the cracks and an unregulated increase in the pressure would cause failure of the chamber.

There is a maximum pressure above which smooth combustion can no longer be sustained and detonations may occur, and a minimum pressure below which stable, consistently smooth burning does not seem possible. Because of the active nature of the chemicals, some propellants deteriorate in storage. This can often be prevented by the addition of chemical stabilizers or inhibitors to the propellant.

In addition to producing a thrust force, solid and liquid propellant engines can be used also for producing auxiliary power and control torques to be applied to the vehicle. This latter is called *thrust vector control* and basically it is usually a mechanical means for altering the direction of the engine's thrust during flight.

Air-breathing Engines. As shown by Figs. 8 to 11, there exist a variety of different types of air-breathing propulsion engines. The range of performance values shown in Table 4 for different types of air-breathing engines are representative and do not correspond to data for specific engines. Each engine is optimized for a specific flight operating condition of speed (Mach number) and altitude. For example the turbojet

TABLE 4. TYPICAL DATA FOR AIRBREATHING ENGINES

Engine Type	Flight Speed (mph)	Altitude (feet)	Cruise Specific Fuel Consumption or Specific Thrust	Thrust to Weight or Power to Wt. Ratio	Typical Applications
Reciprocating Piston engine with propeller	0 - 400 mph	0 - 40,000	0.37 to 0.52 lb hp - hr	1.0 to 2.0	Transport aircraft Small airplanes Helicopters Target drones
Turbojet	0 - 2500	0 - 100,000	1.0 lb lb-hr at M 0.8 1.5 lb lb-hr at M 3.0	0.8 to 1.0 (100 to 400% increase with afterburner)	Bomber, Fighter, Transport aircraft, Target drones
Turboprop	0 - 550	0 - 50,000	0.8 lb hp-hr at M 0.6 0.25 lb hp-hr at M 0	2.0	Fast transport aircraft Small airplanes Helicopters

reducing the velocity. After heating the flow in a combustion chamber, the reverse process occurs adiabatically in the nozzle, where it is desired to attain a maximum exhaust velocity. The efficiency of energy conversion in the inlet duct, nozzle, combustors, compressors, and turbines is a very important factor, and becomes a predominant criterion at supersonic and hypersonic velocities, when compression is achieved usually by a series of oblique shock waves commencing at an inlet spike. To maintain good efficiency and the desired airflow, some diffusers and nozzles incorporate a variable wall contour or cross-section geometry. In general, air-breathing engines have been well developed to a high state of reliability and have given millions of hours of good service.

The available oxygen from the air limits the combustion process. For example, at constant flight speed, the thrust thus decreases with altitude (or oxygen density) and below a combustion pressure of approximately 3 psi, combustion is not easily sustained (flameout limit). Available high-temperature materials will set an upper limit to the maximum combustion temperature at approximately 1700 to 2400 °F. At high speeds and high altitude, the ram-compression of the air causes its temperature to rise substantially, so that the amount of energy that can be added by combustion (without damaging turbine materials) is thus limited; also, special cooling provisions are required.

The simplest air-breathing engine is a *ramjet* (Fig. 8). It does not produce static thrust (at zero flight speed, such as during takeoff) and thus needs a rocket engine or some other engine to bring it to its minimum operating speed.

The *reciprocating piston engine with a propeller* was the very first engine to fly. It is the most economic engine for subsonic flight speed and is used in airplanes and helicopters. The hot gases do work against a piston (not a turbine), which in turn requires a crank mechanism to convert the reciprocating piston motion into shaft rotation. The use of a variable pitch propeller and superchargers for precompression of the inlet air further increase the economy.

The *turbojet* (Figs. 9 and 11) can be designed for a variety of speeds, altitudes and thrust ranges. It often includes special design features such as afterburners (increases the thrust) or bypass duct arrangements with and without a separate compressor called the fan (this improves the fuel economy over certain performance ranges of speed and altitude). This may also include a secondary set of combustion chambers which add heat to the bypass air. An advanced bypass turbojet is shown in Fig. 10.

The *fuel* used is usually a narrow-cut petroleum refinery hydrocarbon product, having the approximate formula of $\text{CH}_{1.95}$. For advanced air-breathing engines, the use of liquid hydrogen fuel offers considerable performance gains.

Advanced Engines. The use of nuclear fission as a source of thermal energy for heating a working fluid promises to give ramjets, turbojets (which

require no combustible fuel) and novel rocket engines with superior specific impulses. The development of such engines faces problems in materials, matching of reactor energy level with the flow level, shielding of radiation, and afterheat disposal, and is currently being investigated. Such a rocket engine using liquid hydrogen as a working fluid and a solid core fission reactor is shown in Fig. 11; it may become useful for manned planetary flight. The use of a nuclear ramjet, now being experimentally investigated, will permit the eventual development of aircraft with theoretically unlimited endurance.

Fusion reactions may someday allow the development of a second type of nuclear engine. They avoid undesirable by-products and could release their energy directly to the working fluid. However, techniques for controlled fusion are yet to be developed.

The use of electrical energy offers further potential increases in rocket engine performance. Electrical propulsion units are discussed separately in ELECTRIC PROPULSION.

Photon propulsion. Solar sail engines rely on the reflection of photons from the sun (radiation pressure at the distance of the earth from the sun is about $5 \cdot 10^{-7}$ kg/m²). Although this force is limited by being directed only "away" from the sun, solar "sailing" can provide low thrusts, and attitude control, turning a spaceship completely around in a few hours. No working fluid is carried in the vehicle.

For the vehicle to carry its own light source, a photon rocket engine of adequate thrust would necessitate energies and techniques far beyond present capabilities.

FLUID DYNAMICS

Fluid dynamics is study of the motion of matter in the gas, liquid, plastic or plasma state. When restricted to flow of incompressible (i.e., constant density) fluids, it is called *hydrodynamics*; when dealing with electrically conducting fluids with magnetic fields present, it is called *magneto-fluid dynamics*; when dealing with practical problems of air flow past airplane wings, through ventilating equipment, etc., it is called *aerodynamics*.

Basically two fundamental approaches are employed: (1) continuum or field dynamics and (2) kinetic theory and nonequilibrium statistical mechanics.

In continuum dynamics, fluid properties—namely, velocity u_i , density ρ , pressure p (more generally stress), temperature T , viscosity, conductivity, etc.—are assumed to be physically meaningful functions of three spatial variables x_1, x_2, x_3 and time t . Two of the four basic equations relating these continuum variables (no electrical current, linear relation between residual stress and rate of strain with viscosity coefficients μ and η' are:

Continuity

$$\frac{\partial(\rho u_i)}{\partial x_i} + \frac{\partial \rho}{\partial t} = 0$$

Motion

$$\begin{aligned} \rho \frac{\partial u_i}{\partial t} + \rho u_j \frac{\partial u_i}{\partial x_j} &= -\frac{\partial p}{\partial x_i} + \eta' \frac{\partial^2 u_i}{\partial x_k \partial x_k} \\ &+ \mu \frac{\partial}{\partial x_j} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + \frac{\partial u_i}{\partial x_k} \frac{\partial \eta'}{\partial x_k} \\ &+ \frac{\partial u_i}{\partial x_j} \frac{\partial \mu}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \frac{\partial \mu}{\partial x_j} \end{aligned}$$

In the above equations, the index notation used for subscripts is that i, j, k may be 1, 2 or 3 representing components of vectors along axes 1, 2 or 3, respectively, and in any term where an index occurs twice, a sum over products is implied. Two additional equations expressing the heat transfer and viscous transfer of energy in forms involving statements of the first and second laws of thermodynamics and the equation of state of the material are required. The four equations, together with boundary conditions, constitute formally a complete set of equations determining p, T, ρ and u_i . For complete discussion and additional equations pertaining to the more general case, see reference 1.

These partial differential equations are nonlinear and have no general solutions even for the most restrictive boundary conditions. Solutions are carried out for very idealized flows. Examples of particular solutions for selected geometrical boundaries are given below.

In Fig. 1, the special flow called Couette flow is indicated schematically. The flow is between parallel plates, lower plate at $y = 0$ at rest, upper plate at y_B moving with constant speed u_B in the x direction. Stress throughout the fluid is constant, given by $P_{xy} = \mu du/dy = \mu(u_B/y_B)$. This is pure shear flow and experimentally is often considered to define and measure the viscosity coefficient μ assumed constant for the homogeneous fluid. The velocity profile appearing at the right in the figure shows by velocity arrows of different length at the various positions y how the velocity varies with position. Steady flow (no dependence of any quantity on time), constant pressure, constant density and laminar flow are additional assumptions for Couette Flow. The flow is realized experimentally by confining the fluid in the narrow annulus between rotating concentric cylinders of nearly equal radius; the cylinders rotate at different speeds.

In Fig. 2, the special flow is in a pipe of uniform cross section, pressure is assumed to be constant across each cross section but to vary linearly with distance x along axis of pipe so $\frac{dp}{dx} = \frac{(p_1 - p_2)}{L}$.

Pistons driving the flow are assumed to be infinitely far away, so that the flow velocity, parallel to pipe axis, has the same dependence upon y and z for all x . The velocity profile is parabolic in both the two-dimensional case (infinite parallel plates) and in the circular cross-section case. Mean flow velocity u_m and viscosity coefficient μ are assumed constant; the flow is assumed steady and laminar. For a circular cross-section pipe of radius a , at any distance r from the center, $u = 2u_m(1 - r^2/a^2)$, and the volume passing a cross section per second is $Q = \pi a^2 u_m = \pi a^4 (p_1 - p_2) / 8\mu L$. Since these formulas do not

FIG. 1. Couette flow.

FIG. 2. Poiseuille flow.

apply near pipe entrances, caution in applying them to pipes of finite length is necessary even when the flow is steady and laminar. (See later discussion of turbulent and laminar flows.)

Other examples of idealized solutions are one-dimensional flow of an ideal gas through a normal shock wave, flow of an ideal gas without viscosity through a pipe of slowly changing cross section (wind tunnel), and one-dimensional finite waves in an ideal gas. Many other solutions involve making whatever approximations and assumptions are necessary to obtain descriptions of observed flows.

In kinetic theory and nonequilibrium statistical mechanics, fluid properties are associated with averages of properties of microscopic entities. Density, for example, is the average number of molecules per unit volume times the mass per molecule. While much of molecular theory in fluid dynamics aims to interpret processes already adequately described by the continuum approach, additional properties and processes are presented. The distribution of molecular velocities (i.e., how many molecules have each particular velocity), time-dependent adjustments of internal molecular motions, and momentum and energy transfer processes at boundaries are examples.

When motion of the fluid consists of only small fluctuations about a state of near-rest, the continuum equations are linearized by neglecting nonlinear terms and become the equations of acoustics². A large variety of fluid motions are described as sound waves; when the small-motion or acoustic description can be used, the *principle of superposition* is valid. This powerful principle allows addition of simple simultaneous motions to represent a more complex motion, such as the sound reaching the audience from the instruments of a symphony orchestra. The superposition principle does not apply to large-scale (nonacoustical) motions, and the subject fluid dynamics (in distinction from acoustics) treats nonlinear flows, i.e., those which cannot be described as superpositions of other flows. The description of small motions in a small region of even a nonlinear flow is useful; at each place in the flow, there is a "local sound speed."

Since sound waves travel with a speed relative to the fluid, waves moving in a moving fluid can sometimes be carried off in a direction opposite to the direction of sound travel. The flow where such a thing happens is called *supersonic*; the flow speed is greater than the sound speed at the spot where the flow is supersonic. Supersonic flow occurs around high-speed vehicles and missiles, and in pipes when high pressure gas escapes through a nozzle into a region of sufficiently lower pressure. A steady supersonic flow always must pass through a *shock front* to slow down to subsonic flow again.

The continuum description of flow fails to describe nearly all actual flows because actual flows when looked at carefully are *turbulent*. Turbulent flows have violent and erratic fluctuations of velocity and pressure which are not associated with any corresponding fluctuations of the

boundaries containing or driving the fluid. Turbulence is generally considered to be the manifestation of the nonlinear nature of the fundamental equations. Under certain conditions as mentioned earlier in describing Couette and Poiseuille flows, nonturbulent or *laminar* flow exists. A common example is cigarette smoke rising from a cigarette held at rest; near the cigarette, the stream is smooth and straight, or laminar, and further up the flow breaks into turbulence.

Reynolds showed that Poiseuille flow in a pipe occurs when $\rho u a / \mu$ is smaller than 2000. The combination of variables is dimensionless and is called the *pipe Reynolds number*. Blood flow in capillaries is laminar, but water flow in household pipes is turbulent unless the flow is about that allowed by a leaky faucet or less. Other types of flow have Reynolds numbers characterizing transition from laminar to turbulent; for example a sphere falling in a fluid of viscosity μ obeys *Stokes Law*

$$mg = 6\pi\mu u$$

where u is the constant speed of fall, m is the sphere mass, a its radius, and g the weight per unit mass, but the law is obeyed only if the *sphere Reynolds number* $\rho u a / \mu$ is smaller than about 1.

Because of turbulence and viscosity, the very simple and useful *Bernoulli formula* is not valid; it can be derived as applying to a constant-density fluid with zero viscosity in laminar flow. However, under certain conditions, the formula applies approximately even when the flow is turbulent, predicting properties within 5 to 20 per cent of the observed values. The Bernoulli formula states

$$p + \rho gh + \frac{1}{2} \rho u^2 \quad \text{same constant in all places in the fluid}$$

where p is the fluid pressure, ρ is the fluid mass density (which must be treated as constant), u is the fluid speed, h is the vertical height above some convenient reference level, and g is the weight per unit mass.

When combined with the equation of continuity, the Bernoulli formula gives a simple description of the Venturi, used in the automobile carburetor (see Fig. 3). Continuity states $u_1 A_1 = u_2 A_2$ volume crossing any cross section of the pipe per second. $u_1 / u_2 = A_2 / A_1$ is small so u_1 is smaller than u_2 . The Bernoulli formula states $p_1 + \frac{1}{2} \rho u_1^2 = p_2 + \frac{1}{2} \rho u_2^2$, and since u_1 is smaller than u_2 ,

FIG. 3. Pipe flow with a constriction; carburetor employing Venturi.

p_1 is larger than p_2 . The atmospheric pressure p_1 pushes the liquid up into the lower pressure region p_2 .

Another common situation described by the Bernoulli formula is the discharge of (constant density) fluid from a small hole. For the cylindrical bucket of water in Fig. 4, equate the sum of the quantities in the Bernoulli formula at the top surface to the sum at the hole: $p_1 + \rho gh + 0 + p_2 + 0 + \frac{1}{2}\rho u_2^2$. The pressure at both top and bottom is atmospheric pressure p_1 ; the speed at the top is approximately zero because the hole is considered to be very small. The predicted speed of the emerging water is therefore $\sqrt{2gh}$ regardless of the size of the hole (as long as the hole is small).

FIG. 4 Discharge through a small hole in a bucket

A valuable instrument in the form of a probe for observing fluid speed is the Pitot tube; its operation is described by the Bernoulli formula. A glass or metal tube with an open end points into the flow, and the pressure difference Δp between the stagnant fluid in the tube and the moving fluid allows calculation of the fluid speed at the place where the tube tip is inserted by $\sqrt{2\Delta p/\rho}$ where ρ is the fluid mass density. When observing air speed, the pressure difference Δp is easily measured by connecting the open ended tube via rubber hose to a glass U-tube water manometer. Errors as much as 50 per cent may easily occur in various practical situations, but order-of-magnitude measurements at least are usually possible.

FLUID STATICS

Statics involves a study of the conditions under which a body remains at rest. If a body of fluid is at rest, the forces are in equilibrium or the fluid is in static equilibrium. The types of force which may act on a body are shear or tangential force, tensile force, and compressive force. Fluids move continuously under the action of shear or tangential forces. Thus, a fluid at rest is free in each part from shear forces; one fluid layer does not slide relative to an adjacent layer. An example is a quantity of water or liquid at rest in a bottle.

Fluids can be subjected to a compressive stress which is commonly called "pressure." The term pressure will be used to designate a force per unit area; pressure units may be dynes per square centimeter or pounds per square foot.

Atmospheric pressure is the force acting on a unit area due to the weight of the atmosphere. "Gage" pressure is the difference between the pressure of the fluid measured (at some point) and atmospheric pressure. The term vacuum refers to pressures below atmospheric. "Absolute" pressure, which can be measured by a mercury barometer, is the sum of gage pressure plus atmospheric pressure.

Pascal's law states that the pressure in a static fluid is the same in all directions. This condition is different from that for a stressed solid (as steel) in static equilibrium; in such a solid, the stress on a plane depends on the orientation of that plane. A liquid in contact with the atmosphere is sometimes called a "free surface." A static liquid has a horizontal free surface if gravity is the only type of force acting.

Imagine a body of static fluid in a gravitational field. The mass of the fluid is m (as in grams) and the weight of the fluid is mg (as dynes) where g is the local gravitational acceleration. Figure 1 indicates a large region of any static fluid with a very small or infinitesimal element. Figure 2

FIG. 1. Large region of any static fluid.

FIG. 2. Vertical forces on infinitesimal element.

indicates the element in detail. The vertical distance z is measured positively in the direction of decreasing pressure (up), dA is an infinitesimal area, p is the pressure acting on the top surface, and $(p + dp)$ is the pressure acting on the bottom surface; the pressure difference is due only to the weight of the fluid element. Let ρ represent density, which is mass per unit volume (as grams per cubic centimeter). Thus the weight of the element is $\rho g dz dA$. Considering the element as a free body, an accounting of forces in the vertical direction gives

$$dp dA = \rho g dz dA \quad dp = \rho g dz \quad (1)$$

As z is measured positively upward, the minus sign indicates that the pressure decreases with an increase in height. This fundamental equation of fluid statics can be applied to all fluids. In integral form, Eq. (1) becomes

$$\int_1^2 \frac{dp}{\rho g} = \int_1^2 dz \quad (z_2 - z_1) \quad (2)$$

where 1 refers to one level and 2 refers to another level. The functional relation between pressure p and the combination ρg must be established before Eq. (2) can be integrated. There are two major cases: (a) incompressible fluids, in which the density ρ is constant and (b) compressible fluids, in which the density ρ varies.

Liquids can be considered as incompressible in many cases. For small differences in height, a gas might be regarded as incompressible. For an incompressible fluid, with constant g , Eq. (2) becomes

$$p_2 - p_1 = \rho g(z_2 - z_1) \quad (3)$$

The term $(z_2 - z_1)$ may be called a static "pressure head," and it can be expressed in feet or inches of water, or some height of any liquid. For example, barometric pressure can be expressed in inches of mercury.

A "manometer" is a device that measures a static pressure by balancing the pressure with a column of liquid in static equilibrium. A large variety of manometers are used, such as differential, vertical, and inclined. The common mercury barometer is essentially a manometer for measuring atmospheric pressure; a mercury column in a glass tube balances the weight of the air above the mercury. Figure 3 illustrates a manometer in which the left leg is open to the atmosphere; the liquid has a specific weight $\rho_2 g$. In the other leg is a liquid of specific weight $\rho_1 g$. Starting with the left leg, the gage pressure p_A at point A is

$$p_A = h_2 \rho_2 g$$

Since the fluid is in static equilibrium, the pressure p_B at point B equals the pressure at point A. Thus

$$p_A = p_B = h_2 \rho_2 g$$

The pressure p_C at point C is less than that at B. Thus

$$p_B - p_C = h_1 \rho_1 g$$

FIG. 3. Manometer.

Then the gage pressure at point C is

$$p_C = g(h_2 \rho_2 - h_1 \rho_1)$$

When a body of any kind is partly or completely immersed in a static fluid, every part of the body surface in contact with the fluid is pressed on by the fluid; the pressure is greater on the areas more deeply immersed. The resultant of all these fluid pressure forces is an upward or buoyant force. The pressure on each part of the body is independent of the body material. Archimedes principle states that the buoyant force equals the weight of the displaced fluid.

Equation (3) is for the special case of an incompressible fluid. As an example of a compressible fluid, consider an isothermal or constant-temperature layer of gas. The equation of state

for such a gas can be written

$$p = \rho RT_1 \quad (4)$$

where T_1 is the given absolute temperature and R is a gas constant or gas factor depending on the gas. Assuming a constant g , Eq. (2) gives

$$\frac{RT_1}{g} \int_1^2 \frac{dp}{p} = (z_2 - z_1) \quad (5)$$

$$z_2 - z_1 = \frac{RT_1}{g} \log_e \frac{p_1}{p_2}$$

Equation (5) is sometimes called a "barometric-height" relation. For an isothermal atmosphere a measurement of the temperature T_1 and the static pressure (as with a barometer) at two different levels will provide data for the calculation of the height difference.

FORCE. *See* STATICS.

FRICTION

Introduction. Friction is the resistance to motion which exists when a solid object is moved tangentially with respect to the surface of another which it touches, or when an attempt is made to produce such motion. Friction thus takes its place as one of the general systems of force which are considered in MECHANICS (others being GRAVITY, ELASTICITY, etc.). Unfortunately friction depends to a marked extent on the material properties of the contacting surfaces, and even more importantly, on any surface contaminants which may be present, so that it is very difficult to estimate values of the friction force theoretically, with an uncertainty of less than about 20 per cent. In many calculations in solid mechanics, this uncertainty in the friction constitutes the limiting factor in determining the accuracy of the over-all calculation.

The friction force arises from the fact that, when two solids are pressed together, bonding between their surface atoms occurs, and these bonds have to be broken before sliding can commence. Bonding of any considerable strength occurs only in places where the surface atoms come within range of each other's strong force-fields (i.e., closer than about 3×10^{-8} cm) thus, when ordinary solids with appreciable roughness are used, bonding is confined to a few small patches (called junctions) over their inter-

face, where the high spots (or asperities) of one material have made contact with asperities on the other material.

The energy used up in the friction process appears almost entirely in the form of heat. Generally this consists of a moderate temperature rise over the contacting bodies, and superposed on this there are higher "flash temperatures" at the junctions. At high sliding speeds, softening or even melting of the tips of the asperities may occur.

In addition to the bonding or "adhesion" effect, which is the principal cause of friction, there are four other mechanisms which use up energy during sliding; energy which must be supplied by the friction force. These mechanisms are:

- (1) A roughness effect, caused by the interlocking of asperities and the need to lift one surface over the high spots of the other;
- (2) A ploughing effect, whereby an asperity on a hard material can dig a groove in a softer material;
- (3) A hysteresis effect, whereby there is elastic and plastic deformation of the material at or near the junctions, and not all the deformation energy is recoverable;
- (4) An electrostatic effect (with electric insulators), where work must be done to separate electrically charged regions on the sliding surfaces.

In a great majority of applications these four mechanisms do not account for as much as 20 per cent of the total resistance to sliding. The widely held belief that friction is due mainly to a roughness effect does not find experimental support. Cleaved mica (smooth to an atomic scale) shows very high friction.

Laws of Friction. If a normal load L presses two surfaces together, then we may apply a tangential force up to some limiting value F_s , and the surfaces will remain at rest. Sliding occurs when the tangential force exceeds the static friction force F_s , and almost as soon as motion starts the tangential force takes on a characteristic value, F_k , and always acts in a direction opposite to the relative velocity of the surfaces. F_s is often some 30 per cent larger than F_k , but sometimes they are equal.

The ratio F_s/L is the static friction coefficient f_s (or μ_s), while the ratio F_k/L is the kinetic friction coefficient f_k . We may cite quite general statements, or "laws," involving these coefficients of friction. The three classical laws, dating back to the seventeenth and eighteenth centuries, are:

- (1) The friction coefficient is independent of the load.
- (2) The friction coefficient is independent of the contact area.
- (3) The kinetic friction coefficient is independent of the sliding velocity.

More recently, it has been found possible to make another general statement about the friction coefficient:

- (4) The friction coefficient is independent of the surface roughness.

We may summarise these laws in the comprehensive statement.

(5) The friction coefficient is essentially a material property of the contacting surfaces, and of the contaminants and other films at their interface.

Although in practice these "laws" are reasonably well obeyed, there are often systematic divergencies, some of which have important consequences. In the rare cases in which the friction coefficient varies with load, it is often because of some special effect (e.g., a surface coating which is broken up at heavy loads); however, materials with a high elastic limit (e.g., polymers) generally show a friction coefficient which goes down somewhat as the load is increased. The fourth law applies closely to the intermediate ranges of surface roughness, but it is found that very smooth surfaces have higher friction because they tend to seize, and very rough surfaces have higher friction because of asperity interlocking.

Velocity and Time Effects in Sliding. Violations of the third friction law are important because they can lead to friction-induced oscillations. With some materials f_k is almost independent of velocity over a very wide range; however, with hard materials the friction generally goes down as the speed goes up (a so-called negative characteristic), while soft materials show a negative characteristic at high sliding speeds and a positive characteristic at low sliding speeds. Often, f_k changes by about 10 per cent during a factor-of-ten change of velocity. In a sliding system which has elastic compliance, a negative characteristic introduces an instability, and at high speeds this takes the form of harmonic oscillations (e.g., a violin string), while at low speeds relaxation oscillations occur (e.g., a creaking door). The relaxation oscillations are usually referred to as stick-slip, because during a part of each cycle the surfaces are at rest. The severity of the stick-slip is enhanced because, while the surfaces are at rest, f_s increases somewhat with time of stick (about 10 per cent for every factor-of-ten increase in time of stick above 10^{-1} seconds).

Value of the Friction Coefficient. In most situations the total real area of contact, or sum of all the asperities, is produced by plastic deformation of the asperities, and if we assume that strong bonds are formed joining the materials across the interface we find that the friction

coefficient is given by

$$f = s/p$$

where s is the plastic shear stress, and p the plastic indentation hardness, of the softer of the two contacting materials. Since s and p are similar plastic strength parameters, their ratio tends to be constant, within the range 0.3 to 0.6, for a wide variety of materials. With some materials the real area of contact increases during sliding, and friction coefficients above 1.0 are then commonly observed. Especially bad in this connection are materials with a high ratio of surface energy to hardness, namely clean soft metals such as lead, aluminum and copper.

A lubricant acts by introducing a layer of lower shear stress s_1 at the interface, and lowers the friction coefficient accordingly, down to 0.05 in favorable cases. Many nominally clean materials also give low friction, as result of contamination during manufacture or handling. Slight differences in the degree of contamination can produce drastic differences in the friction.

Some typical friction values are given in Table I.

Materials with Unusual Frictional Properties. In this category we may place the hard non-metals (diamond), which give low friction (~ 0.1); the elastomers (natural rubber) which give very high friction (~ 0.9); the layer-lattice substances (graphite, molybdenum disulfide, cadmium iodide) which give low friction (~ 0.1) and are used as solid film lubricants; the hexagonal close-packed metals (zinc, magnesium, titanium, cobalt) which when clean give lower friction coefficients (~ 0.5) than do other metals; "Teflon," which adheres very poorly to other solids and accordingly gives very low friction (~ 0.05); and metals in group IVb of the periodic table (titanium, zirconium, hafnium) which cannot be well lubricated by any known liquid substances. Generally, the frictional anomalies of solids may be traced to peculiarities in their structure or surface properties.

Related Fields of Interest. Friction is considered one of a group of mechanical surface interaction phenomena, and research in the other members of the group is of great interest to workers in the friction field. There is an extensive common literature. The other interaction phenomena are wear (the removal of surface material as result of mechanical action), lubrication (the properties

TABLE I. COEFFICIENTS OF FRICTION

Materials	Surface Conditions	f_s	f_k
Metals on metals (e.g. steel on steel, copper on aluminum)	Carefully cleaned	0.4-2.0	0.3-1.0
	Unlubricated, but not cleaned	0.2-0.4	0.15-0.3
	Well lubricated	0.05-0.12	0.05-0.12
Nonmetals on nonmetals (e.g., leather on wood, rubber on concrete)	Unlubricated	0.4-0.9	0.3-0.8
	Well lubricated	0.1-0.2	0.1-0.15
Metals on nonmetals	Unlubricated	0.4-0.6	0.3-0.5
	Well lubricated	0.05-0.12	0.05-0.12

of surface films which reduce friction and wear), and adhesion (the tendency of solid objects pressed together to remain together).

FUSION

Introduction. When nuclei of certain light elements fuse together, there is an excess binding energy which appears in the form of heat. This is the energy source of both the sun and the hydrogen bomb, and it is the object of fusion research to liberate the energy in a controlled manner on earth; because of the abundance of light elements, such power is virtually unlimited.

In order to promote nuclear fusion, the reacting nuclei must have sufficient inertia to overcome their mutual coulomb repulsion. Thus nuclei with a high ratio of mass to charge, such as deuterium and tritium, heated to a high temperature are most suitable. The reaction of interest is

where the numbers in parenthesis are the energies of the reaction products. The cross section (σ) peaks at about $5 \times 10^{-24} \text{ cm}^2$ and deuteron energy of 107 KeV, liberating a total energy of 17.6 MeV and giving an energy gain of 160. This is emphasized by noting that 8 gallons of seawater contain 1 gram of deuterium, which yields a maximum of $8 \cdot 10^{10}$ calories on fusion, equivalent to 2500 gallons of gasoline or 80 tons of TNT. Many methods have been proposed, but are as yet untested, for harnessing this energy. Among these are the generation of electric current by the interaction of the charged helium particles with a magnetic field, the dissipation of the neutron energy as heat in a water jacket, using the neutrons to release fission energy in uranium placed round the fusion reactor (making a combined fusion, fission reactor), and the generation of steam power by using the heat radiated from the hot gases.

Although the cross section peaks at a directed deuteron energy of 107 KeV, it is possible to use a much lower mean energy if the nuclei are thermalized. This is because there is an exceedingly sharp rise of cross section with energy and most of the fusion reactions are produced by nuclei with energies far in the tail of the Maxwellian distribution. For example, in a thermal mixture of deuterium and tritium most of the reactions are produced by deuterium of energy $1.3 \times 10^{-4} T^{2/3} \text{ KeV}$ (where $T^\circ \text{ K}$ is the temperature). Even so, the temperature required is extremely high, typically near 10^8° K .

Plasma in a Fusion Reactor. At such high temperature, atoms are ionized by collisions and the electrons are not bound to any particular nucleus; this state of matter is called a plasma. Since stars are in the plasma state, plasmas are by far the most common form of matter in the universe (though they are rare on earth) and the problems of controlled thermonuclear fusion are closer to astrophysical plasma physics than nuclear physics.

Because of the unbound electrons, plasmas are good electrical conductors and a magnetic field cannot easily diffuse through them (the "skin depth" in a hydrogen plasma after a time t is $3 \times 10^6 t^{1/2} T^{-1/2} \text{ cm}$). While the diffusion proceeds there is a current induced in the plasma skin which interacts with the field to cause a pressure perpendicular to the field lines of $\sim B^2/8\pi$ atmospheres, where B is the field in kilogauss; effectively the plasma pressure is balanced by the field pressure which is supported by the magnet coils generating the field. Thus the magnetic field affords the means of insulating the plasma from the material walls against which it would rapidly cool.

Often, as the result of the method of forming the plasma or because of field diffusion, magnetic field becomes mixed with the plasma. The confining magnetic field pressure must then balance the sum of the plasma pressure and the pressure of the field in the plasma. In this connection, an important parameter of the plasma is β , the fraction of the confining field pressure that supports the plasma pressure, which varies from 0 to 1 as the field inside the plasma goes from the confining field to zero. For a particular plasma pressure, the lower the β , the more the confining field and the more the energy required to operate the magnet.

Operating Regime. The operating regime of a fusion reactor is determined by the variation of the reaction cross section with temperature, the economics of energy conversion into useful work, and material properties such as the strength of the magnet metal, vaporization of the wall of the containment vessel, etc. Energy balance in the reactor gives a minimum requirement for the product nt where t is the reaction time and n is the number of nuclei per cubic centimeter. If the total energy released in the reaction vessel (the nuclear energy plus the energy of the plasma particles plus energy radiated) is returned with an efficiency of 1/3 to maintain the plasma temperature and make up the radiation losses, then nt must be greater than 10^{14} and the minimum temperature is about $3 \times 10^7^\circ \text{ K}$. For this minimum condition, 1 per cent of the nuclei fuse together. Also, since the reaction rate depends on n^2 , too high an n rapidly leads to wall vaporization and too low an n to a negligible rate. If we assume that a power density of 100 watts/cc can be handled continuously (equal to present fission reactor levels), n must be $\approx 10^{16}$ nuclei/cc (about a thousandth of an atmosphere); this is probably correct to within an order of magnitude, being on the low side for pulse operated, highly

compressed plasmas that fill only a small fraction of the reaction vessel. The condition $nt > 10^{14}$ then demands that $t > 10$ msec, and for a $\beta = 1$ plasma a confining field of 34 kilogauss.

If the helium from the fusion reaction is trapped in the plasma, its energy can maintain the plasma temperature against losses by radiation. This avoids the inefficiency of recycling the fusion energy to heat more plasma. The minimum temperature for this approach, called the "ideal ignition temperature," is 4.6×10^7 °K. All the energy of the neutrons from the fusion reaction can then be applied to produce useful power.

Radiation. One of the many problems to be solved in devising a fusion reactor is that of radiation at these high temperatures. Fortunately, the plasma required is so diffuse that it does not act as a blackbody which would follow a fourth-power law of temperature for the radiant energy ($6 \times 10^{-13} T^4$ watts/cm²). Instead, the radiation mean free path is larger than the plasma dimensions and the dominant radiation process is caused by electrons deflected in the coulomb field of the nuclei. This is called bremsstrahlung and peaks in the soft x-ray region at a wavelength of around 1 Å. The power radiated is $0.54 \times 10^{-30} Z^2 n_e n_i T^{1/2}$ watts/cc (Z = nuclear charge; n_e and n_i are electron and nuclear density) which is proportional to the square root of the temperature and, for reasonable sized reactors, is far less than blackbody radiation. However, even hydrogenic bremsstrahlung is considerable and an increase of two orders of magnitude could kill the concept of fusion reactors. Because of the $n_e Z^2$ factor, ionized impurities could produce a serious radiation loss; for instance, only 1 per cent of ionized oxygen increases the radiation by 77 per cent. Impurities also absorb a disastrous quantity of energy during ionization, not only because of the ionization potential of the electrons but also in the excitation of the partially ionized atoms by free electrons with insufficient energy to produce complete ionization; this excitation energy is radiated a few nanoseconds after excitation. It is therefore very important to ionize impurities rapidly.

A further important mechanism of energy loss in the plasma is charge exchange produced between a neutral impurity molecule (liberated, for instance, at the wall of the vacuum vessel by the radiation) drifting into the plasma and donating an electron to a hot ion. The hot ion now becomes neutral, is no longer held by the magnetic field, and is lost from the plasma. Meanwhile the cold impurity ion absorbs plasma energy in being further ionized and heated, and the hot neutral particle bombards the wall to liberate further impurities.

Therefore because of both radiation and charge exchange every effort is made to produce a highly pure plasma, typically with an impurity level of less than 0.1 per cent. This is difficult considering the low operating density and the high temperatures involved.

Plasma Heating. For temperatures up to a few million degrees, the conductivity of the plasma

is sufficiently small for ohmic heating to be effective. Above these temperatures, the conductivity ($8 \times 10^{-6} T^{3/2}$ mhos/cm) becomes too large and other forms of heating must be used. Ohmic heating is often used as preheating so that when a magnetic field is later applied to the plasma surface it exerts a pressure rather than diffusing into the plasma.

A common method of heating is to compress the plasma with the magnetic field; the energy put into the plasma is then

$$\int_{V_1}^{V_2} p \, dv$$

where p is the magnetic field pressure and $V_1 - V_2$ is the volume change. The volume change is limited by the size of the magnet, so it is desirable to use a high value of p . In the "Theta" and "Z" pinch experiments the gas is heated in a cylindrical tube first ohmically, then by a powerful magnetic pressure. The magnetic field is produced by current from a very low inductance, high voltage capacitor energy store. The compression is then so rapid that shock fronts develop in the plasma; subsequently isentropic compression is produced by raising the field still further. Temperatures of the order of 10^7 °K are commonly quoted, and even 10^8 °K has been claimed for late in the life of the plasma. A method of obtaining high plasma compressions without large volumes of magnetic fields is to transfer the plasma into successively smaller magnets as the compression increases. The transfer is achieved in an experiment called "Toy Top" by using a larger field at one end of the plasma than at the other.

Another method of heating the plasma by magnetic compression without large volume changes is magnetic pumping. The plasma is alternately compressed and decompressed at one point on its length, and the problem is to choose conditions in which the plasma does not cool on decompression (that is, an irreversible cycle is required). The heating depends on the pumping period compared to the ion/ion collision time and the transit time of an ion through the pumping region. If the pumping period is of the order of the transit time and much shorter than the collision time, the ions gain energy while the field is increasing and leave the region before decompression. The heating is then proportional to $T^{3/2}$ and becomes more effective at high temperatures. This system and ion cyclotron heating (another system depending on oscillating magnetic fields) are being tested on the "Stellarator" experiment to bring ohmically heated plasma up to thermonuclear temperatures.

A third important means of forming the plasma is to accelerate individual nuclei in an electrostatic field, then inject them into the confining magnetic field. This has the advantage that high particle energies (on the order of tens of keV) are relatively easy to produce, but the problem of injecting the nuclei is difficult because it is not possible in general to trap the nuclei in a static magnetic field under conservative conditions. The

procedure is to change the particle orbit discontinuously either by a collision against background plasma or by altering the charge-to-mass ratio. For collision with background plasma, a very long path length is required: in the "Sinelnikov" experiment this is achieved by carefully angling the injection down a long cylindrical field with regular ripples along its length and high "mirror" magnetic fields at the ends, so that the particles are reflected back and forth between the mirrors and the ripples cause the particles on their first return to avoid the injection gun. In the "D.C.X. Mirror" experiment, fast D_2^+ molecules are injected, and dissociated in an arc. In the "Phoenix Mirror" and "Alice Mirror" experiments, excited neutral atoms are injected which are ripped apart when they reach the magnetic field because, due to the difference in charge, the negative electrons and positive ions in the atom gyrate in opposite directions (this is called "Lorentz" trapping).

Confinement. One of the difficulties of confining a plasma with a magnetic field is to eliminate end loss down the plasma axis. One way is to increase the magnetic field at the plasma ends so that the field lines bend towards the axis. In a collision-dominated high-density plasma, a mode of operation of the "Ft-1" pinch, the system then acts like a gas trapped in a double ended rubber balloon. Due to the curvature at the ends there is a component of force parallel to the axis which reflects the particles; this is called a collision-dominated magnetic mirror. However, even a very small amount of field accidentally mixed in the plasma will prevent the ends from closing completely and allow particles to escape. It is estimated that a field in the plasma of only 1 per cent (equivalent to $\beta = 0.999$) will produce an unacceptable loss.

Another type of magnetic mirror is the collision-free mirror. This is used with a low- β plasma when the ions gyrate around the magnetic field lines and move along them because of axial components of velocity gained by collisions. When the particles reach the collision-free mirror region there is again a component of magnetic force parallel to the axis which, if the axial energy is not too great, will reflect the particle back to the main plasma volume. A certain fraction, depending on the coulomb collision cross section, of the particles gains axial energy sufficient to overcome the mirror and is lost. The collision cross section varies inversely as the square of the particle energy ($= 2.6 \times 10^{-18}/W^2 \text{ cm}^2$ where W is the particle energy in keV) and is always greater than the fusion cross section, so the majority of nuclei make coulomb collisions before fusion collisions. Even so, it is possible that sufficient fusion collisions can occur for the reactor to be economical. One method of reducing the effect of end loss is to make the reactor very long so that the end area is a small fraction of the total plasma area.

A further method of avoiding end losses is to join the ends forming a plasma loop. This is,

however, unstable since the confining field lines are more closely bunched on the inside of the loop compared to the outside, the pressure is higher on the inside and the plasma drifts outwards. To avoid this, the "Stellarator" experiment uses a figure-eight shaped plasma mixed with magnetic field. Then plasma moving along a field line tends to drift in opposite directions at opposite loops of the figure eight, so if the particle flow around the tube is more rapid than the drift in each loop, the total drift is zero.

Stability. The stability of the plasma/field system is an extremely important factor in the success of a fusion reactor and is the subject of many experiments. A prevalent form of instability is the "flute" or "interchange" in which the plasma develops deep ridges parallel to the field lines. The condition for these ridges to develop is that the field lines are curved with the centre of curvature inside the plasma so that the intensity of the field falls off from the plasma surface. This is a cause of instability in the "z-pinch" and in some regions of the mirror geometry. To prevent this instability, it has been suggested that the field be mixed in the plasma at a skew angle to the confining field. Then, for the instability to develop and the plasma and confining field to be interchanged, the internal skew field has to be stretched and turned, requiring energy; thus, under certain theoretical conditions the plasma should be stable. However experiments with z-pinches show such a system still to be unstable for reasons which are not clear. It may be that finite plasma resistance is affecting the stability criteria.

One method of making the mirror system stable, used by Ioffe, is to add a hexapole field produced by a series of six bars placed parallel to the axis equally spaced around a circumference. Opposing currents flow in alternate bars producing a magnetic field which falls off with distance from the bars. Thus the system has a minimum of magnetic field at its centre and increasing field both radially and towards its mirror ends, and plasma at the center experiences a curved field in all directions with the center of curvature always outside the plasma. This is now recognized to be a particular case of a general class of field geometries called minimum B configurations which are inherently stable against hydromagnetic flute instabilities. Preliminary experiments show a large increase in containment time when the Ioffe bars are in operation.

Another form of flute instability may grow when the plasma is accelerated, as in a rapid magnetic compression or by centrifugal forces if the plasma rotates. These are similar instabilities to the gravitational instabilities of a mercury/water layer, with mercury above, first investigated theoretically by Rayleigh. The origin of the rotation is not definitely understood, but it is known that again the Ioffe bars also suppress these instabilities.

A further and important class of instabilities, the "velocity space" instabilities, can arise for particular conditions of plasma β if the plasma is

not thermalized so that the mean energy parallel to the field lines differs from the energy perpendicular to the lines. When the perpendicular energy is the greater, the plasma tends to form bunches, called "mirror instability," and when the parallel energy is the greater, the plasma wriggles like a fire hose—"fire-hose instability".

These examples of instability are given to illustrate the many types that can occur. It is obvious, however, that the lower the plasma β (so that the vacuum field is approached), especially with a minimum B configuration, the more stable is the plasma.

Conclusions. Only a few problems of fusion research have been mentioned and demonstrated by reference to some of the many experiments proceeding in the field. The main centers of research are Russia (35 per cent of total effort), the United States (25 per cent), Great Britain (10 per cent), and the rest are in Europe. The cost of the research in the United States is about 25×10^6 dollars/yr, in Great Britain, 10×10^6 dollars/yr, in Europe, 6.2×10^6 dollars/yr.

At present (1964), the theta pinch has the greatest nT of 10^{12} at densities of 10^{16} to 10^{17} and temperatures $\approx 10^7$ K. The major difficulties are particle loss from the ends, radiation and plasma rotation. Injected mirror experiments have the highest energy (~ 10 to 100 keV), but only low densities of $\sim 10^{10}$ have been attained because of instabilities. Great hopes are centered around the application of minimum B field configurations to the injection mirror experiments.

G

GAS LAWS

The term "gas law" refers to the thermodynamic equation of state of a gas, which is an equation relating the pressure p , the volume V , the absolute temperature T , and the number of moles ν . The equation of state is a valid relation when and only when the gas is in a state of thermodynamic equilibrium; the pressure and temperature are then constant and uniform throughout the volume occupied by the gas.

Ideal or Perfect Gas. The ideal or perfect gas is defined thermodynamically by the two conditions: (1) it obeys the equation of state: $pV = \nu RT$ where R is the gas constant per mole ($R = 8.3169 \times 10^7$ erg mole⁻¹ C⁻¹), and (2) the internal energy U is independent of pressure and volume and is a function only of the temperature ($(\partial U/\partial V)_T = 0$). The statistical-mechanical definition of an ideal gas is that it is a gas of noninteracting molecules, i.e., the molecules exert no appreciable forces of attraction or repulsion on each other. Since the notion of a finite "size" of a molecule connotes the existence of a repulsion which prevents two molecules from overlapping each other, the molecules of an ideal gas must be of negligible "size." The two thermodynamic properties can be deduced from the statistical mechanical definition.

The ideal gas equation: $pV = \nu RT$ embodies the experimental laws of Boyle, Charles and Gay-Lussac. It can be derived either from kinetic theory or from statistical mechanics. It is often written in the form: $p = nkT$ where n is the molecular number density and k is Boltzmann's constant ($k = 1.3804 \times 10^{-16}$ erg C⁻¹). In the case of a mixture of inert, ideal gases, each gas obeys the equation: $p_i = n_i kT$ where p_i and n_i are, respectively, the partial pressure and partial density of the i th component gas. Boyle's law will not hold if the gases in the mixture react chemically, since a change in p or V will in general change the value of ν .

Real or Imperfect Gas. The ideal gas law is, of course, only an approximation which holds at temperatures sufficiently far above the critical temperature and at sufficiently low densities. The ordinary properties of bulk matter in the liquid and solid states require the existence of strong intermolecular repulsions which endow the molecules with a finite "size" and also require the existence of attractive forces to hold the molecules

together. The equation of state of a real gas is therefore determined by the nature of the intermolecular forces. One of the earliest, simplest, and most useful equations is that of van der Waals

$$\left(p + \frac{a}{V^2}\right)(V - b) = RT \text{ (for 1 mole)} \quad (1)$$

where a and b are constants, determined empirically for each gas, which are related to the attractive and repulsive forces, respectively. This equation can be related theoretically, in first approximation, to a molecular model in which the molecules are represented by rigid elastic spheres that weakly attract each other. The van der Waals equation accounts qualitatively for the liquid-vapor phase transition. The constants a and b can be determined from critical point data.

Other equations of state for an imperfect gas have been proposed which are more accurate than the van der Waals equation, e.g., the equations of Dieterici, Berthelot, Beattie-Bridgeman, and Benedict-Webb-Rubin. These empirical equations are useful in treating the thermodynamic properties of gases at high densities. At low densities, the empirical equations have been superseded by the virial equation of state

$$\frac{pV}{RT} = 1 + \frac{B(T)}{V} + \frac{C(T)}{V^2} + \frac{D(T)}{V^3} + \dots \text{ (for 1 mole)} \quad (2)$$

where $B(T)$, $C(T)$, and $D(T)$ depend on the nature of the gas and are called the second, third and fourth virial coefficients, respectively. The departures of a gas from ideality are represented in this case by a power series in the density. We may rewrite Eq. (2) as

$$p/kT = n + \hat{B}(T)n^2 + \hat{C}(T)n^3 + \hat{D}(T)n^4 + \dots \quad (3)$$

where \hat{B} , \hat{C} , \hat{D} are the virial coefficients referred to one molecule.

The basic experimental problem in this field is to measure the virial coefficients of different gases as functions of the temperature. The higher-order coefficients beyond $B(T)$ and $C(T)$ are very difficult to measure. The basic theoretical problem is to calculate the virial coefficients from an assumed form for the intermolecular potential

energy and, ultimately, to derive the intermolecular potential from quantum mechanics.

Statistical Mechanics of the Imperfect Gas. The derivation of the virial equation of state from the intermolecular potential involves several steps which may be summarized as follows:

The two routes indicated are via the canonical and the grand ensembles. The most difficult step is the evaluation of the configuration integral:

$$Q_N = \int \cdots \int \exp[-\Phi(r_1, r_2, \dots, r_N)/kT] dr_1 dr_2 \cdots dr_N \quad (4)$$

where Φ is the total intermolecular potential energy of the gas of N molecules. The proper way to evaluate Q_N was first sketched by Ursell and later carried through by Mayer who assumed central forces that were pairwise additive, i.e.,

$$\Phi = \sum_{i < j} u(r_{ij})$$

where $u(r_{ij})$ is the potential between molecules i and j . Neither of these assumptions is correct, but they appear to be good approximations, and with their aid, it is possible to evaluate Q_N rigorously in terms of the so-called cluster integrals, b_l , which are integrals over the coordinates of l molecules only. $B(T)$ is obtained directly from b_2 , $C(T)$ is obtained from b_3 and b_2 , and the l th virial coefficient requires evaluation of the cluster integrals up through b_l . Explicit formulas for $\hat{B}(T)$ and $\hat{C}(T)$ are:

$$B(T) = -\frac{1}{2V} \iint f_{12} d\tau_1 d\tau_2 \quad (5)$$

$$\hat{C}(T) = -\frac{1}{3V} \iiint f_{12} f_{23} f_{13} d\tau_1 d\tau_2 d\tau_3 \quad (6)$$

where $f_{ij} \equiv \exp[-u(r_{ij})/kT] - 1$. Higher coefficients in the virial series are increasingly more difficult to evaluate.

The calculations just described are based on the classical Maxwell-Boltzmann statistics and are sufficiently accurate for most gases at ordinary temperatures. However, in the case of the lightest gases H_2 and He and especially at low temperatures, it is necessary to introduce quantum corrections in the equation of state.

Intermolecular Forces and the Equation of State. In order to calculate the cluster integrals and virial coefficients, one must first choose a form for the intermolecular potential $u(r)$. In principle, the potential $u(r)$ is determined by quantum mechanics for any pair of molecules and could be found by solving the Schrödinger equation. In practice, this is virtually impossible, and quantum-mechanical calculations have been made only for the very simplest molecules. In the case of interactions between neutral, nonpolar, spherical

molecules, e.g., noble-gas atoms, the quantum-theoretical interaction energy can be approximately decomposed into several parts, of which the two most important are the *dispersion energy* and the *valence repulsion energy*. The former corresponds to the van der Waals attraction and the

latter to the van der Waals repulsion. The dispersion energy varies inversely with the sixth power of the distance. The valence-repulsion energy takes account of the short-range repulsion that sets in when the electron distributions of the two molecules begin to overlap, and it is associated with the Pauli exclusion principle. There is no simple, general form for the dependence of the valence repulsion potential on the distance; it is often empirically represented by Ae^{-ar} or by μr^{-n} where $n \geq 12$ is commonly used. In the case of molecules that possess permanent electric dipole or quadrupole moments, there are additional contributions to the van der Waals attraction but these are usually less important than the dispersion energy (H_2O is an exception).

In the absence of a complete quantum-mechanical expression for the intermolecular potential, it is necessary to approximate the potential by a semi-empirical formula, containing one or more adjustable constants, which is chosen on the grounds of physical plausibility and mathematical convenience. The semi-empirical force law is then used to calculate macroscopic properties that are known from experiment, and the parameters in the force law are adjusted to give the best agreement with experiment. Given the form of the intermolecular potential, it is possible to calculate not only the virial coefficients in the equation of state but also the kinetic-theory transport coefficients (i.e., the viscosity coefficient, the thermal conductivity, and the various diffusion coefficients of the gas) and the density, compressibility, and sublimation energy of the solid. A particular functional representation of the intermolecular potential can be considered satisfactory only if it is possible to secure agreement with all experimental data involving a particular pair of molecules with a single choice of the parameters that appear in the law of force.

The semiempirical law that is most frequently used to represent the interaction between nonpolar molecules is the *Lennard-Jones* (12, 6) potential:

$$u(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^6] \quad (7)$$

where ϵ and σ are parameters characterizing the particular pair of molecules. This simple two-parameter function, when inserted in Eq. (5), predicts a temperature variation of the second virial coefficient in good agreement with experiment. The same potential also explains the temperature variation of the viscosity coefficient over

a substantial temperature range, but the agreement is poor for the highest experimental temperatures. Third virial coefficients calculated from Eq. (6) do not agree with experiment at the lowest temperatures. Calculations of virial coefficients and transport coefficients of gases and of equilibrium properties of the crystal lattices have also been made for other simple semiempirical potential functions, but the results are not very different from those found with the (12, 6) potential.

Further advances in this field will come, on the theoretical side, from a more detailed knowledge of the intermolecular forces, and on the experimental side, from more accurate ways of measuring the virial coefficients.

Dense Gases. High-density gases cannot be conveniently represented by the virial equation of state because of the slow convergence of the virial series. Furthermore, the theoretical evaluation of the higher virial coefficients on the basis of any plausible molecular model would meet with great computational difficulties. Other approaches are therefore needed, e.g., the empirical equations of state already mentioned and the principle of corresponding states. In the latter method, one introduces the reduced, dimensionless variables: p/p_c , $V_r = V/V_c$, and T/T_c where the subscript c refers to the critical point. The principle of corresponding states then asserts that all substances obey the same equation of state in terms of the reduced variables. The variables may also be reduced in terms of intermolecular potential parameters.

A promising theoretical approach to the equation of state of a dense gas or liquid is provided by the method of the radial distribution function $g(r, n, T)$. Because of intermolecular forces, the actual density at a small distance r from a given molecule is different from the bulk density n and is represented by $ng(r, n, T)$. Thus the radial distribution function measures the effect of intermolecular forces on the probability of finding two molecules close together. While it is difficult to determine $g(r, n, T)$ theoretically, it can be found experimentally from the diffraction pattern observed when x-rays are scattered by the fluid.

GASES: THERMODYNAMIC PROPERTIES

Fundamental Principles. The thermodynamic properties of a substance may be classified as either reference properties, energy functions, or derived properties.¹ The reference properties of a single component system are pressure, volume, temperature, and entropy. For a specific amount of a pure gas, it is necessary to specify only two of these reference properties to fix the state of the system and its properties. For mixtures of gases the composition must also be specified to completely fix the system. The energy functions are internal energy, U ; enthalpy, H ; Helmholtz free energy, A ; and Gibbs free energy, G . These functions represent the energy available for performing useful work under various process conditions. Derived properties include specific heat, fugacity, activity coefficient, compressibility factor, and the Joule-Thomson expansion coefficient.

Properties are termed intensive if they are independent of the amount of the material. Examples are pressure and temperature. Properties such as volume and entropy, which are dependent on the amount of material, are termed extensive.

Absolute values may be determined for the reference properties, but the energy functions must be determined relative to an arbitrary zero reference point. The internal energy, U_0 , of the ideal gas at the absolute zero of temperature is generally taken as the zero reference point of the enthalpy and free energy functions. Other reference points include a zero value for the enthalpy of the ideal gas at the ice point, $H_{273.15}$, and another in which the sensible enthalpies are combined with chemical energies.² In the latter base, the value of $H_{298.15}$ is zero for the assigned reference elements so that the values of $H_{298.15}$ for the various compounds are equal to their heats of formation from the assigned reference elements.

Thermodynamic properties of gases are calculated for both the ideal gas state and the real gas state. A gas is defined to be ideal if it follows the simple equation of state, $PV = RT$. Gases behave in this manner only at very low pressure, but the ideal gas state is a convenient reference state for the calculation of the thermodynamic properties. Thus, the thermodynamic standard state³ is defined as the ideal gas at unit pressure at each temperature, and it is denoted by a superscript degree mark as in H° and S° . The ideal gas properties have been calculated for many substances, but the real gas properties are known for relatively few substances.

Thermodynamic properties are used in the calculation of energy balances, reaction compositions at chemical equilibrium, reaction temperatures, and the work involved in the compression or expansion of gases in various systems.

Ideal Gas Properties. The thermodynamic properties of an ideal gas such as C_p° , $(H^\circ - H_0^\circ)/T$, S° and $(G^\circ - G_0^\circ)/T$ are calculated from theoretical equations and from an analysis of spectroscopic and molecular structure data.⁴ These complex calculations are based upon the contributions from all of the energy states available to the molecule, such as translational, electronic, vibrational, and rotational. Contributions from excited electronic states are important for diatomic molecules at higher temperatures but are entirely negligible for most polyatomic molecules. Vibrational energy levels are obtained from an analysis of infrared and Raman spectroscopic data by applying the principles of wave mechanics and group theory.^{4,5} The interpretation of the spectra includes the assumption of a model for the molecule with parameters such as bond lengths, bond angles, and force constants. The parameters are varied within certain limits until the best agreement with observed spectra is obtained. Rotational energy levels are observed in infrared, Raman, and microwave spectra. The rotational energy includes not only the rotation of the molecule as a whole but also internal rotations by groups of atoms within the molecule and a pseudorotation in some ring molecules.⁶

For higher orders of accuracy in the calculation of the thermodynamic properties, additional contributions may be determined that are caused by the interaction between vibrational and rotational motions, centrifugal distortion of the molecule during rotation, and anharmonicity of the vibrations. Another contribution due to nuclear spin can be, and generally is, neglected for all molecules except H_2 and D_2 since it causes a detectable effect on measurable quantities only at very low temperatures. Adjustments are made for the presence of isotopes in some diatomic and polyatomic molecules.

The calculation of the thermodynamic properties of an ideal gas is based not only on theory but also on accurate experimental vapor heat capacity, heat of vaporization, and low-temperature calorimetric data.⁶ The ideal gas heat capacity C_p° and entropy S° are derived from these data and are compared to theoretical values. When differences are found, the theoretical calculations are revised until there is good agreement. In this manner, new information is gained about the conformation of the molecule, its frequencies of vibration, etc. Thus, experimental data provide a firm base to test theoretical calculations and improve the calculation of all of the thermodynamic properties.

Theoretical calculations become increasingly complex as the molecular size increases. Thus, a method of increments has been devised to calculate the thermodynamic properties of large molecules based on an "anchor compound" for a given homologous series.^{1,7}

Real Gas Properties. The thermodynamic properties of real gases are determined primarily from experimental compressibility (pressure-volume-temperature) measurements (see COMPRESSIBILITY, GAS). All other properties are calculated either from equations of state or from a correlation of the individual experimental data points. In addition, the properties may be estimated from generalized correlations of the compressibility factor ($Z = PV/RT$).

Experimental compressibility measurements have been made by a variety of methods⁸⁻¹⁰ such as constant volume cells (Euken and Meyer), variable volume cells (Beattie and Douslin, Michels, and Sage and Lacey), expansion systems with variable sample mass (Burnett), and differential systems (Whytlaw-Gray). The apparatus of Beattie and Douslin is used to measure both isometrics and isotherms up to 350°C and 400 atmospheres. The Michels apparatus may be used up to 3000 atmospheres but is limited to a temperature of 150°C. Sage and Lacey have made extensive measurements on both gas and liquid systems up to 240°C and 670 atmospheres.

Equations of state have been derived from compressibility data to represent the behavior of a gas over wide ranges of temperature and pressure.^{8,11} Numerous equations have been published but one of the most important is the virial equation,

$$PV = RT(1 + B_1V + C_1V^2 + D_1V^3 + \dots) \quad (1)$$

It is quite important because the parameters B , C , D , etc., are related to the interactions between molecules according to the intermolecular potential energy theory. Other equations having wide applications are those of Beattie and Bridgeman and of Benedict, Webb, and Rubin (see GAS LAWS).

The energy functions, entropy, and heat capacity of a real gas are calculated as the sum of the ideal gas properties and a correction for the non-ideality of the gas. The corrections for the non-ideality of the gas are called difference or departure functions. For example, $S - S^\circ$ is the entropy of the gas in the real state less that of the gas in the standard state at the same temperature. Theoretical equations needed for the computation of the thermodynamic properties have been derived in terms of pressure, volume, temperature, and the first derivatives $(\partial V/\partial T)_p$ or $(\partial P/\partial T)_v$.¹¹

For example:

$$H - H^\circ = \int_v^\infty [P - T(\partial P/\partial T)_v]dv + PV - RT \quad (2)$$

The heat capacity differences $C_p - C_p^\circ$ and $C_v - C_v^\circ$ are functions also of the second derivatives $(\partial^2 V/\partial T^2)_p$ or $(\partial^2 P/\partial T^2)_v$ depending upon whether the equations are written in terms of P and T , or V and T . The quantities appearing in Eq. (2) are usually evaluated from equations of state. However, the most accurate properties are those which are calculated from an analysis of

isometric and isothermal P - V - T data.¹² The slopes of the isometrics $(\partial P/\partial T)_r$ are found by analytical, residual, and graphical techniques. The integrals as in Eq. (2) are integrated graphically or numerically.

Extensive correlations of data have been made to develop methods for estimating the properties of gases.^{1,11} One method based on the theory of corresponding states presents the thermodynamic properties as a function of reduced temperature ($T_r = T/T_c$), reduced pressure ($P_r = P/P_c$), and the compressibility factor, Z_c . The subscript c refers to the critical state.

Gas Mixtures. The thermodynamic properties of a mixture of gases may be calculated, but the procedures are only approximate unless compressibility data are available for the particular mixture.^{8,11} Since few data for mixtures are available, the properties must be estimated from: (a) the equations of state of the pure gases assuming either additive volumes or additive pressures, (b) an equation of state for the mixture, or (c) generalized correlations of the compressibility factor based on pseudoreduced conditions.¹

GEODESY

Geodesy comprises the determination of the earth's external form and gravitational field, and the location of points with respect to earth-fixed reference systems. The earth's external form is customarily defined by the geoid: the equipotential of the earth's gravity field which most closely approximates the mean sea level.

The geoid is irregular in form, so that the mathematical representation thereof is necessarily an approximation. The most important approximation is an oblate ellipsoid of revolution, which is conventionally defined by its equatorial radius, a , and the flattening, f , equal to $(a - b)/a$, where b is the polar semidiameter. Location is conventionally expressed in coordinates referred to such an ellipsoid, in terms of the latitude ϕ , the angle between the normal to the ellipsoid and the equator; the longitude λ from the reference meridian, Greenwich; and altitude h above or below the ellipsoid.

If the ellipsoid is considered to be rotating with rate ω , and to be an equipotential for the combined effects (called gravity) of centrifugal and gravitational acceleration, additional parameters customarily required are γ_e , the acceleration of gravity at the equator; and m , the ratio of the centrifugal acceleration at the equator, $\omega^2 a$, to γ_e . γ_e and m are connected to the total mass M contained in the ellipsoid by:

$$kM = a^2 \gamma_e [1 - f + 3m/2 - 15mf/14 + O(f^3)] \quad (1)$$

where k is the constant of GRAVITATION ($6.664 \times 10^{-8} \text{ cm}^3 \text{ g}^{-1} \text{ sec}^{-2}$). The customary formula for the acceleration of gravity γ at geodetic latitude ϕ is:

$$\gamma = \gamma_e [1 + (5m/2 - f - 17mf/14) \sin^2 \phi + (f^2/8 - 5mf/8) \sin^2 2\phi + O(f^3)] \quad (2)$$

The customary formula for the gravitational potential external to the ellipsoid is:

$$V = \frac{kM}{r} \left[1 - J_2 \left(\frac{a}{r} \right)^2 P_2(\sin \phi) - J_4 \left(\frac{a}{r} \right)^4 P_4(\sin \phi) - O(f^4) \right] \quad (3)$$

In Eq. (3), V is written as positive, which is the convention of astronomy and geodesy, contrary to that of physics. In Eq. (3), P_2 and P_4 are Legendre Polynomials, and

$$J_2 = 2f(1 - f/2)/3 - m(1 - 3m/2 - 2f/7)/3 + O(f^3) \quad (4)$$

while J_4 is usually taken as a quantity determined observationally from satellite orbits.

The discrepancies in location of the actual geoid and a well-fitting ellipsoid are nearly always 10^{-5} or less of the radius vector, while the discrepancies in intensity of the gravitational acceleration from that of the standard ellipsoid are nearly always 10^{-4} or less of the total intensity. The mathematical representation of these discrepancies may either be in the form of spherical harmonic coefficients or in the form of mean values for areas; the former being preferable for effects on satellites in orbit, and the latter for use of terrestrial data. The potential theory dealing with the relationship between variations in the location of the geoid and the intensity of gravitational acceleration is known in geodesy as Stokes' theorem.

There are five principal systems of measurement in geodesy.

(1) Horizontal control comprises the determination of the horizontal components of position—latitude and longitude—starting from fixed values for a certain point. It includes measurement of distances over the ground by metal tapes or by pulsing or modulating radio or light signals, and measurement of angles about a vertical axis by theodolites. Over the land, the relative horizontal position of points is obtained either by triangulation—a system of overlapping triangles with nearly all angles measured, but only occasional distances measured; or by traverse—a series of measured distances at measured angles with respect to each other; or by trilateration—a system of overlapping triangles with all sides measured. Much of the land area of the world is covered by triangulation, which gives the difference in latitude and longitude between points in the same network with a relative error of about 10^{-5} .

(2) Vertical control comprises the determination of heights, which is performed separately from horizontal control because of irregularities in atmospheric refraction. The most accurate method, leveling, measures successive differences of elevation on vertical staffs by horizontal lines of sight taken at intermediate points over short distances (less than 150 meters) balanced so as to minimize differential refraction effect. The datum to which vertical control refers is mean sea level as determined by tide gages. The accuracy is such

that the error in difference of elevation between points on the same principal network should be a few tens of centimeters or less.

(3) Geodetic astronomy comprises the determination of the direction of the gravity vector and the direction of the north pole at a point on the ground. Astronomic longitude is the angle between the meridian of the gravity vector and the Greenwich meridian and is determined by measuring the time of intersection of a line of sight by a star. Astronomic latitude is the angle between the gravity vector and the equatorial plane, and is determined by measuring the maximum altitude attained by a star. In these types of astronomic observation, several stars are normally observed which are selected so as to minimize error due to atmospheric refraction. Astronomic azimuth is determined by the measurement of the horizontal angle between a target and Polaris or other reference star.

(4) Gravimetry comprises the determination of intensity of gravitational acceleration. Most gravimetric observations are made differentially, by determining the change, with change in location, of the tension on a spring supporting a constant mass. These measurements are connected through a system of reference stations to a few laboratory determinations of absolute acceleration of gravity. The relative accuracy of gravimetry is about $\pm .001 \text{ cm sec}^{-2}$ on land and $\pm .005 \text{ cm sec}^{-2}$ at sea. The principal difficulty in its geodetic application is irregular distribution of observations.

(5) Satellite tracking comprises the determination of the directions, ranges, or range rates of earth satellites from ground fixed stations. These observations will be affected both by errors in positions of the station with respect to the earth's center of mass and by perturbations of the orbit by the earth's gravitational field; hence, in conjunction with a suitable dynamical theory for the orbit, they are used to determine the position of tracking stations and the variations of the gravitational field. To minimize refraction effect, directions are determined by photographs of the satellite against the background of fixed stars. Satellites can also be used as elevated targets by simultaneous observations from several ground stations.

The principal practical application of geodesy is to provide a distribution of accurately measured points to which to refer mapping, navigation aids, engineering surveys, geophysical surveys, etc. The principle scientific interest in geodesy is the indication of the earth's internal structure by the variations of the gravity field.

Numerical values of the leading geodetic parameters are given in Table 1.

GEOPHYSICS

Geophysics is the physics of the earth and the space immediately surrounding it and the interactions between the earth and extraterrestrial forces and phenomena. It consists of a number of interlocking sciences dealing with physical properties of the earth, its interior and atmosphere, its age, motions and paroxysms, and their practical applications. All of these sciences use the methods of physics for measurements and analysis. From observational material, often of an indirect nature, attempts are made to derive abstract models of states and processes through advanced mathematical concepts and, in some cases, through statistical relations.

Geophysics is an ancient science. In its early stages it was developed by the Greeks who attempted to determine the shape and size of the Earth (Eratosthenes, 275–194 B.C.). Among its most illustrious contributors have been Galileo Galilei (1564–1642); Sir Isaac Newton (1642–1727) who dealt with the motions of the earth and its gravitational field; Karl Friedrich Gauss (1777–1855), who developed the theory of the magnetic field; and Vilhelm Bjerknes (1862–1951) who laid the foundation for the hydrodynamic theories of the atmosphere and the oceans. During the current century, its roster of distinguished scientists includes: L. Vegard (polar aurora); Sidney Chapman (aeronomy); C.-G. Rossby (meteorology); H. U. Sverdrup (oceanography); Sir Harold Jeffreys; F. A. Vening-Meinesz (structure of the earth); and B. Gutenberg and J. B. Macelwane (seismology).

A major milestone in the development of the science was the International Geophysical Year (IGY), followed by the International Geophysical Cooperation, from 1957–1959, when over 8000 scientists of 66 nations collaborated in a coordinated attack on the remaining physical mysteries of our planet. The IGY gave birth to man's most spectacular ventures to date: the launching of artificial earth satellites and the conquest of the icy wastes of the Antarctic continent in the quest for solutions of important geophysical problems. IGY took place during an interval of high solar activity and was followed in 1964–65 by the year of the quiet sun (IQSY) to cover the whole range of solar influences on the earth (see INTERNATIONAL GEOPHYSICAL YEAR AND INTERNATIONAL YEARS OF THE QUIET SUN).

A brief survey of the various subfields of geophysics follows:

Geochronology is the study of the age of the earth and its various geological formations. Inadequate earlier methods of sedimentology have been replaced by the use of radioactive decay constants and isotope ratios. This has made it possible to date approximately all major geological eras. For the oldest rocks, the decay of U^{238} to Pb^{206} has led to ages of around 3×10^9 years.

GEODESY deals with the size and shape of the earth and its gravitational field. Because of the rotation of the earth, its lack of absolute rigidity, crustal mass distribution, and tidal forces, the shape is not spherical but approximates that of a triaxial ellipsoid. The polar diameter is shorter than the equatorial. This polar flattening has been determined by measurements on the surface, lunar observations and, since, 1958 satellite motions. The best estimate of the flattening is 1:298. The actual figure of the earth, which is irregular, is referred to as the *geoid*, which represents an isopotential surface. The undulations of the geoid have been determined by gravity measurements. The measured values of gravity depend on latitude because of the flattening and the variation of the centrifugal force from pole to equator. The normal value of gravity at the earth's surface in centimeters per second per second, is represented by

$$\gamma = 978.0516[1 + 0.005291 \sin^2\phi - 0.0000057 \sin^2 2\phi + 0.0000106 \cos^2\phi \cos 2(\lambda + 6^\circ)]$$

where ϕ and λ are latitude and longitude, respectively.

Gravity measurements have shown that in spite of large mass differences at the surface, the earth is nearly in isostatic equilibrium. Various crustal blocks act as if they floated in a dense subcrustal material. The undulations of the geoid do not exceed 80 meters. Approximate dimensional figures for the earth are: surface area $510.1 \times 10^6 \text{ km}^2$; volume $1,083 \times 10^9 \text{ km}^3$; average density 5.517 g/cm^3 ; mass 5.975×10^{27} grams; equatorial radius 6,378.163 km.

The deformations of the solid earth by tidal forces form a specialty. The twice daily occurring *tides* are observed by deflections of the vertical or variations of gravity. For the lunar tide, the variations amount to about 0.168 milligal, for the sun to 0.075 milligal. (One milligal equals 10 microns per sec per sec.) The maximal elevation of the geoid is 36 cm, the largest depression 18 cm, for the lunar effect; the total solar tide can reach 25 cm. The combined total at new and full moon is 79 cm.

Geomagnetism deals with one of the most important physical characteristics of the earth. Its magnetic field is about 1/2 gauss in strength. It consists of an internal part, about 9/10 of the total and an external part of 1/10. The internal part is assumed to originate from electromagnetic fields caused by differential rotation between the earth's core and its mantle. The external part is caused by an ionospheric ring current. The field can be represented by a dipole, which fluctuates in direction both in time and space. Short-periodic fluctuations are brought about by solar disturbances which cause invasions of protons and electrons into the high atmosphere. These disturbances, which follow broadly solar activity as expressed by sunspots, cause minor and major fluctuations of the earth's magnetic field. The major disturbances, called magnetic storms, can be observed worldwide. The same particle bombardments cause the *polar aurora* through excitation of oxygen, hydrogen, and nitrogen atoms in the high atmosphere. Much slower variations of the magnetic field are tied to the internal field and possibly connected with convective currents. Paleomagnetic evidence indicates that the magnetic poles are not fixed and that the field has reversed direction several times during the earth's history. In the present era, the magnetic poles and poles of rotation do not coincide.

It has been hypothesized that the migration of the magnetic poles is also an indication of migrations of the inertial axis of the earth. The distribution of the field over the surface of the earth has been mapped in form of the total intensity, the horizontal and vertical intensity, the inclination and declination. The latter is of great practical importance for use of magnetic compasses in direction finding. The influence of the earth's magnetic field extends outward into space for many earth radii. It influences the path of invading particles and is responsible for the configuration of the van Allen belts.

SEISMOLOGY deals with the study of earth-

quakes. Most of them can be attributed to breaks in the earth's crust. A few may be subcrustal and caused by phase transformations. Some minor ones are associated with collapse of cavities and volcanic eruptions. All of them are characterized by sudden release of elastic waves. These are longitudinal, transverse, Rayleigh or Love (surface) waves. Through analysis of their travel time from the point of origin of receiving seismograph stations, they permit deduction of the layering and elastic constants of the interior of the earth. Like other waves, earthquake waves can be reflected and refracted upon entering a different medium. The internal constitution of the earth has been derived primarily from seismic evidence. This reveals an upper and lower crust, an upper and lower mantle, and the core. The boundary between crust and mantle was first discovered by A. Mohorovičić in 1909. The depth is variable. In some oceanic areas, it may be only 5 km; in continental areas, it is usually 30 to 40 km and the maximum is estimated at 60 km. The quest for knowledge about the petrographic constitution of the mantle has led to the project attempting to drill in one of the suboceanic thin crustal areas to the Mohorovičić discontinuity, the so-called Mohole. The boundary of the core is about 2900 km deep. The density in the mantle is from 3 to 6 g/cm³, that of the core from 10 to 17 g/cm³. The temperature of the interior has been variously estimated at 1500 to 4000 C. Earthquakes are primarily tied to areas of geologically recent mountain formation, the great island arcs, and the adjacent great rifts. The same areas usually show also the greatest contemporary volcanic activity.

Volcanology deals with some of the most spectacular phenomena in geophysics. They include explosive eruptions, lava flows, gaseous exhalations, magma intrusions, geysers and hot springs. Study of the earth's active volcanoes revealed that release of tectonic pressure may lead to volcanic eruptions, but no reliable systems of forecasting impending volcanic activity have yet been devised. The greatest eruption within human memory was that of Krakatoa on May 20, 1883 which threw about 4 km³ dust into the air up to stratospheric levels. This dust stayed in suspension for over two years, interfering with the earth's heat balance. Some hypotheses of climatic fluctuations are based on the varying intensity of eruptive volcanism during the earth's history.

METEOROLOGY and *Aeronomy* are concerned with the physical state and the motions of the atmosphere, which is divided into a number of layers. The lowest is the troposphere with an average thickness of 7 to 8 km in polar regions and 13 km in the equatorial zone. Temperatures decrease to the interface, called tropopause, with the next layer the stratosphere. At the tropopause, polar temperatures average around -55°C , in equatorial regions -80°C . In the stratosphere, temperatures stay nearly isothermal with height and increase again above 25 km. Above the stratosphere are the mesosphere and ionosphere, and the outermost layer, the exosphere, gradually fades into the

plasma continuum between earth and sun. In these higher layers of the atmosphere, complex interactions between the fluxes of electromagnetic radiation of various wavelengths and corpuscular radiation from the sun on one side and the low-density concentrations of atmospheric gases on the other side take place. The particulate radiations are also governed by the earth's magnetic field. Radiations of short wavelength cause a variety of photochemical reactions, the most notable of which is the creation of a layer of ozone acting as an effective absorber of solar ultraviolet and thus causing a warm layer at 30 km in the atmosphere. The upper atmosphere as an absorber of primary cosmic rays shows many interesting nuclear reactions and is an important natural source of radioactive substances including tritium and carbon 14 which are used as tracers of atmospheric motions and as criteria of age.

Most manifestations of weather take place in the troposphere. They are governed by the general atmospheric circulation which is stimulated by the differential heating between tropical and polar zones. The resulting motions in the air are subject to the laws of fluid dynamics on a rotating sphere with friction. They are characterized by turbulence of varying time and space scale. Evaporation of water from the ocean and its transformation through the vapor state to droplets and ice crystals, forming clouds and precipitation, are important symptoms of the weather-producing forces (see METEOROLOGY).

Hydrology studies the water cycle on the earth in detail. It includes the runoff from precipitation, the surface courses of water and their floods, the deposited forms of water as snow and ice, and the return of water to storage underground or the ocean. The study of glaciers and their mass budget is an important phase of this field and contributes to the as yet speculative hypotheses about ice ages.

Oceanography has a broad overlap with both meteorology and hydrology. It includes the study of wind-driven waves and currents, and the storage and release of heat to the atmosphere. The tidal motions and their dependence upon configuration of ocean basins and coastal lines were among the earliest geophysical phenomena observed and analyzed by man. They were also the first to be predicted by a computer. The density differences of ocean waters, predicated on temperature and salinity, cause three-dimensional internal circulations in the deeper ocean layers. Much of this remains to be observed and explained. Of great practical importance to inhabitants of shore lines are the *tsunamis* which are gravity waves caused by underwater earthquakes. Because their movement is much slower than that of elastic seismic waves, warnings can be issued through prompt evaluation of seismic records.

Geophysical Prospecting is based on physical methods derived from the study of earthquakes and magnetic and gravitational fields. These procedures, highly refined, are being used in the discovery of mineral resources. Inhomogeneities

in the crust caused by inclusions of different physical characteristics can be noted from the surface by local anomalies of the magnetic or the gravitational field. Miniature earthquakes produced by explosions will disclose layering, salt domes and other geological features. Distortion of artificially created electric fields also can lead to ore bodies or similar anomalies. Interpretation of radioactivity observed at the surface or in boreholes also permits geological deductions. Extremely sensitive apparatus, especially for magnetometric mapping, can be used from the air and permits rapid surveying of vast areas.

GRAVITATION

Gravitation is the phenomenon characterized by the mutual attraction of any two physical bodies. This universal character of the gravitational force was first recognized by Sir Isaac Newton who also gave its quantitative expression. For point masses or spherical bodies a simple expression results:

$$F = \frac{GM_1M_2}{R^2} \quad (1)$$

In addition to the masses M_1 , M_2 of the two bodies and their distance apart R , the force depends only on a constant $G = 6.670 \times 10^{-8}$ dyne cm² gm⁻² which is independent of all properties of the particular bodies involved. The same force law describes the motion of the planets around the sun, of the moon around the earth, as well as the falling of an apple to the earth. A body moving under an inverse square law as given in Eq. (1) satisfies the three laws established by Kepler for the motion of the planets around the sun:

(1) The planets move in elliptical orbits with the sun at one focus (the general orbit is a conic section) (Fig. 1).

(2) The radius vector sweeps out equal areas in equal times.

(3) The square of the period of revolution is proportional to the cube of the semi-major axis: $a^3 = (2\pi)^{-2} GM_{\odot} T^2$. Here M_{\odot} is the mass of the sun and T is the period of the planet.

These results together with a detailed analysis of anomalies in the motion of the moon established the correctness of the Newtonian theory of gravitation (see KEPLER'S LAWS).

FIG. 1. An elliptical orbit for a planet around the Sun. The shaded areas indicate equal areas swept out in equal times at different parts of the orbit. Clearly, the speed of the planet varies with its position in its orbit.

Recently, careful calculations have been carried out to determine the orbits of the artificial satellites which have been launched by the United States and the Soviet Union. These have required modifications in the force law Eq. (1) to take into account the deviation of the earth's figure from a sphere and the anisotropy of the earth's density as well as the atmospheric drag. The success of the space program to date is an additional tribute to Newton's genius. Other calculations study powered space flight in order to examine possible orbits for exploration of the Solar System. There is every reason to believe that Newton's gravitational theory is sufficiently accurate for this purpose. Einstein's modification of the theory, to be described below, will probably have little effect on our space program for some time to come.

The *weight* of a body of mass M on the earth is the force with which it is attracted to the center of the earth. On the surface of the earth the weight is given by

$$W = Mg$$

where the *acceleration due to gravity* is obtained from Eq. (1):

$$g = \frac{GM_E}{R_E^2} = 980 \text{ cm/sec}^2 = 32 \text{ ft/sec}^2$$

All freely falling bodies near the surface of the earth are accelerated at the same rate g . It is for this reason that Galileo found that both light

and heavy objects take the same time to reach the ground when dropped from the Leaning Tower of Pisa.

An astronaut is said to be in a state of *weightlessness* when he is in orbit. Strictly speaking, he still has weight for the earth's gravity still acts on him. Otherwise he would fly off into outer space. However, when in free fall, the local effects of the gravitational field are eliminated for the astronaut. Objects which are released fall together with him and hence remain in his vicinity unlike the situation on the ground. Therefore, the organs of the body respond as though the gravitational field were absent and this gives the sensation of weightlessness.

Gravitational Field. According to Newtonian theory, the sun exerts the gravitational force directly on the earth without an intervening medium for transmitting that force. The behavior of such forces is called "action at a distance." To overcome the conceptual difficulty of a force acting directly over large distances, one assumes that a *gravitational field* fills all space. The force acting on any mass is determined by the gravitational field in its neighborhood. Thus, at the point P a distance R from the center of the earth, the gravitational field has the magnitude

$$\mathcal{G} = \frac{GM_E}{R^2}$$

and magnitude of the force on a mass M at P is simply $F = M\mathcal{G}$. Note that the field is to exist at P even in the absence of the mass M .

It is sometimes convenient to introduce the gravitational potential which determines the field through its gradient. For a spherical earth, it is defined as

$$\phi = -\frac{GM_E}{R}, \quad \mathcal{G} = -\text{grad } \phi$$

In general ϕ will satisfy Poisson's equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} = 4\pi\rho \quad (2)$$

ρ is the density of matter. The potential energy of a mass M , in the field is simply expressed in terms of ϕ ,

$$V = M\phi$$

Although one can introduce the gravitational field, it is an auxiliary concept in Newtonian theory for the field has no independent dynamical behavior as is true of the electromagnetic field (e.g., electromagnetic waves). At any time, the Newtonian gravitational field is determined by the configuration of masses at that instant and does not depend on previous history or state of motion. Thus if the sun were to vanish, the gravitational force on the earth would immediately be removed. This property may be thought of in terms of an infinite velocity of propagation for the gravitational field. Letting the velocity of light become infinite in Maxwell's equations eliminates all independent dynamical behavior for

the electromagnetic field. In that case there could be no radio or television. The special theory of relativity which is based on the velocity of light in vacuum being the maximum velocity for the transmission of energy, implies that Newton's theory requires modification.

Principle of Equivalence. The mass of a body may be measured either by weighing $W = Mg$ (*gravitational mass*) or by observing its motion under a known applied force using Newton's second law of motion $F = MA$ (*inertial mass*). The equality of these two differently defined masses has been measured by R. H. Dicke to an accuracy of $1 \cdot 10^{-11}$ improving an earlier measurement by Eötvös. It is this equality which distinguishes the gravitational force from all other forces in giving all bodies the same acceleration. The discussion of weightlessness pointed out that local effects of the gravitational field are eliminated for an observer in free fall precisely because all bodies fall at the same rate. It follows that the gravitational field *measured* by an observer will depend on his state of motion. In a sense *there is an equivalence between a gravitational field down and an acceleration up for the observer*. However, the equivalence is not complete, for real gravitational fields converge on their sources so that two particles released at the same time will drift closer together as they fall. On the other hand, acceleration fields have no effect on the separation of particles moving on parallel paths (Fig. 2). In a curved space, initially parallel geodesics—the "straight lines"—do not maintain a constant separation (e.g., great circles on a sphere). Thus, the gravitational field may have its explanation in the geometry of a curved space-time.

FIG. 2. The paths of particles released in

- (a) An acceleration field (the acceleration is up, the apparent force is down).
- (b) A gravitational field showing convergence toward the source.

Red Shift. According to the quantum theory, a photon of frequency ν has an energy $h\nu$ (h is Planck's constant), and by the relation $E = mc^2$, this quantum has a mass $m = h\nu/c^2$. To lift a mass m a height H requires expenditure of the energy mgH . Therefore, a photon emitted at the surface of the earth arrives at the height H with the energy

$$h\nu - (h\nu/c^2)gH = h\nu\left(1 - \frac{gH}{c^2}\right) = h\nu'$$

At the surface of the earth, the frequency shift amounts to

$$\frac{\Delta\nu}{\nu} = 1.1 \times 10^{-16}H \text{ (H in meters)}$$

This shift was measured by Pound and Rebka using the Mössbauer effect in good agreement with the prediction. As time standards are determined by frequency, it follows that if the same photon were emitted at the height H , it would be measured to have the frequency ν , not ν' . Therefore, an observer at H must conclude that his clock is running faster than the same clock would run on the surface of the earth in the ratio $\Delta T/T = -\Delta\nu/\nu$ (Fig. 3).

FIG. 3. Photons are emitted on the ground and are received at the height H . Between the two dotted lines representing the beginning and end of a pulse, the same number of oscillations, n , are received at H as are emitted at the ground level. Because of the red shift, the interval t' between oscillations at H is greater than the interval t between oscillations on the ground. Therefore, the time measured at H for the reception of the n oscillations is greater than the time required for their emission on the ground: $nt' > nt$. This result implies that clocks run faster at H than on the ground.

Einstein's theory of gravitation. Albert Einstein assumed that gravitation is a physical effect produced by the curvature of a four-dimensional space-time. The generalization of Newton's gravitational potential is the metric tensor $g_{\mu\nu}$ in terms of which the four-dimensional distance, and hence the geometry of space-time, is determined:

$$ds^2 = \sum_{\mu, \nu=1}^4 g_{\mu\nu} dx^\mu dx^\nu$$

The curvature of space-time is defined in terms of a four index tensor $R^\mu{}_{\nu\rho\sigma}$, the curvature tensor. The vanishing of the curvature tensor means that no real gravitational field is present. The field equations are ten linear combinations of the curvature components which are of the second order in the derivatives of the metric tensor and are a

generalization of Poisson's equation [Eq. (2)]. Symbolically these equations are written

$$G^{\mu\nu} = 8\pi\kappa T^{\mu\nu}$$

where $T^{\mu\nu}$ is a symmetric tensor which describes the distribution of matter and energy throughout space-time and $\kappa = G/c^2$. In a weak field static approximation, these equations contain Newton's theory of gravitation with the Newtonian gravitational potential. Given by $2\phi = 1 - g_{44}$.

The metric tensor outside a static spherically symmetric mass distribution is given by the Schwarzschild solution:

$$ds^2 = \left(1 - \frac{2\kappa m}{r}\right) dt^2 - \left(1 - \frac{2\kappa m}{r}\right)^{-1} dr^2 - r^2 d\theta^2 - r^2 \sin^2 \theta d\phi^2$$

This geometry exhibits the red shift described above and in addition shows two other effects:

(1) The bending of a ray of light passing near the sun's edge by

$$\delta\theta = 1.75''$$

(2) The precession of the perihelion of Mercury by

$$\delta\phi = 43''.03 \text{ century}$$

These results agree with the observations within the experimental errors which are fairly large—about 10 per cent.

Gravitational Waves. Einstein's field equations require that the gravitational field have a finite velocity of propagation—the same as that for light. Therefore, the gravitational field has independent dynamical degrees of freedom, which permit gravitational waves to exist in two modes. In passing through matter, one mode produces a compression along one axis and corresponding elongation along the perpendicular axis (Fig. 4); the other mode has the same effect along axes rotated by 45° . This character for the modes is caused by the tensor nature of the potentials $g_{\mu\nu}$, which limits the lowest order of gravitational waves to quadrupole radiation. A crude estimate of the energy radiated by the earth-sun system per year amounts to 10^{16} ergs (about 10^6 kWh). Radiating at this rate, the earth has lost about 10^{15} of its available mechanical energy since its formation 5×10^9 years ago.

Presumably there are stronger sources of gravitational waves available in the universe such as super novae, and the quasi-stellar sources. Experiments are in preparation by J. Weber of the University of Maryland to monitor gravitational waves received from the cosmos.

Quantum Theory. The gravitational interaction among the elementary particles is down by a factor of 10^{-40} from the electromagnetic or strong nuclear interactions. Therefore, one cannot expect to observe quantum effects at the level of today's experiments. Nonetheless, because the

FIG. 4. (a). A circular arrangement of dust particles before a gravitational wave arrives.

(b). The same particles after a passage of a wave consisting of one mode. The second mode would produce the same effect, rotated at 45° .

gravitational field has two independent modes, the quantum field formalism requires that the gravitational field operators exist and satisfy appropriate commutation relations. Although there is no difficulty in principle, the gravitational field equations are complicated by being non-linear and by their covariance under arbitrary coordinate transformations. However, from its linear approximation, one expects that the quantized field will be a spin 2 boson field. Furthermore, because of its connection with the geometry of space-time, the gravitational field will be a link among all particles and all interactions.

Cosmology. One expects the gross structure of the universe to depend on global geometrical properties and the mean distribution of matter more than on the detailed kinetics of particle interactions. Among the various cosmological solutions of Einstein's equations are those models based on a homogeneous and isotropic matter distribution in which matter is streaming away from every point with a velocity proportional to its distance from that point. Such models agree with the observation made by Hubble which give a recessional velocity

$$v = Hr$$

with $H = 30$ km/sec/ 10^6 light-years and r measured in millions of light years. This value of H leads to an age for the universe of about 10^{10} years.

Recently some extremely luminous, relatively small, but very distant, objects have been observed. The most luminous of these quasi-stellar sources is 3C 273 at 1.6×10^9 light-years. This distance is so great that it is possible that a very early stage in the development of galaxies is being observed. The amount of energy being released is so great ($\sim 10^{46}$ ergs/sec) that a nuclear source for the energy is ruled out, and it is suggested that the energy comes from the gravitational contraction of $10^{10} M_\odot$ down to its characteristic radius of $2\kappa m = 2 \times 10^{10}$ km. This subject is under intensive research today.

GYROSCOPE

The gyroscope consists of a flywheel or a sphere that is spinning (usually at high speed) about an axis. If this axis is free in space (such freedom may be provided by gimbals, by floating the spinning mass on a column of gas or fluid, or by suspension in a magnetic or an electrostatic field), the axis will remain parallel to its original position even though the gyroscope is mounted on a vehicle that translates and rotates in three dimensions. This property of the "free gyro" often referred to as "spatial memory" was used as an artificial horizon as early as 1744 by Serson. This permitted a ship's navigator to take readings with a sextant (measurement of the angular elevation of a star with respect to the horizon) when the horizon was obscured by darkness, fog mist, etc. This early instrument has led to the modern vertical gyro.

In 1852, Leon Foucault built one of the first precise gyroscopes. Utilizing a flywheel only a few inches in diameter supported in near-frictionless gimbals, this instrument was sensitive enough to detect the rotation of the earth. This free gyro maintained a fixed orientation in space as the earth turned. The relative motion was observed through a microscope.

In 1896, the gyroscope saw its first application for guidance when Obry used it in a self-propelled torpedo. An *unguided* torpedo, under the influence of winds, currents, and ocean waves would *not* follow a prescribed course. The gyroscope, on the other hand, was pointed at the target before launching the torpedo, and by means of linkages connected to the spin axis support, it actuated the rudder of the torpedo, steering it along a straight course.

When the gyroscope is *not* free, that is, when the spin axis is forced to turn in space, the gyroscope develops a torque about an axis that is perpendicular to the plane containing the spin axis and the axis about which turning takes place.

This property was utilized to find north by continually reorienting the spin axis until the gyroscope could *not* detect the *rotation* of the earth. This instrument, called the gyrocompass, was perfected in 1908 by Anschutz of Germany and by Elmer Sperry (1911) of the United States. This instrument used a wheel four to eight inches in diameter, and was suspended in such a way that it tended to remain vertical. Since the vertical turned with the earth, the gyroscope following it produced a torque. This torque, in turn, was used to provide self-turning of the spin axis in a direction that would reduce the torque. In the final equilibrium position, the instrument pointed north. The gyrocompass is still widely used today.

The gyroscopic torque is also used to stabilize ships. Due to the motion of waves, the *unstabilized* ship rolls considerably. It is impractical to shift huge masses fast enough to counteract the irregular motion. On the other hand, a gyroscope develops torque instantly and with much less effort. This led to the development of the gyroscopic ship stabilizer. Utilizing a wheel 10 to 20 feet in diameter, and a hydraulic turning mechanism, angular rates are applied to the spin axis support producing tremendous gyroscopic torques upon the ship. In moderately rough seas, the gyro stabilizer can eliminate 70 to 80 per cent of the roll motion. The control signal to the turning mechanism is provided by a small "vertical gyro" which is very much like Serson's artificial horizon gyro. This essentially is a guidance system (like Obry's) using a small guidance gyro to provide the vertical and a large gyro to provide the action.

If the motion of the gyro is free, and if a torque is applied to the structure containing the spinning mass, it will turn or precess about an axis that is perpendicular to the plane containing the torque axis and the spin axis. This is the converse of the gyroscopic torque phenomenon. By adjusting the amount of torque, the gyroscope provides a controlled rate. This property is utilized in an autopilot during a constant rate of turn. The principle is also used for platform stabilization where the platform carries instruments which must bear specific orientations with respect to the earth. By carefully regulating the torque, the gyroscope and platform rotate with the earth without being in contact with the earth.

Inertial navigation is accomplished by a gyroscopic system combining all the phenomena previously mentioned. Inertial navigation is required whenever visual or radiation methods cannot be used as the link with the earth. In its simplest form, this system consists of a free gyro platform that can be torqued. Prior to making the journey, the platform is leveled. As the ship, submarine, or missile circles the earth, accelerometers mounted on the platform continuously measure vehicular acceleration. This is integrated twice to determine the distance traveled. Dividing by the radius of the earth computes the angular position on earth (latitude and longitude). The gyroscope performs one of these integrations, and by appropriate scaling of the torque mechanism,

it divides the radius of the earth, tilting the platform through angles equal to the change in latitude and longitude. Thus, the system becomes an accurate analog of the motion of the vehicle on the earth.

In the more sophisticated inertial navigation systems, redundant measurements are made to minimize the growth of errors over long periods of time.

H

HALL EFFECT AND RELATED PHENOMENA

If a current of particles bearing charges of a single sign and constrained to move in a given direction is subjected to a transverse magnetic field, a potential gradient will exist in a direction perpendicular to both the current and the magnetic field. This phenomenon is called the Hall effect, after E. H. Hall who discovered it in a metal in 1879.

Principles Involved. The Hall effect is a manifestation of the Lorentz force on a charged particle, which is expressed by the vector equation

$$\mathbf{F} = e[\mathbf{E} + (1/c)\mathbf{v} \times \mathbf{H}] \quad (1)$$

where \mathbf{F} is the force, e the charge, and \mathbf{v} the velocity of the particle, \mathbf{E} is the electric field, and \mathbf{H} is

the magnetic field intensity. A permeability of unity is assumed, and for the gaussian system of units, c is the speed of light. The physics involved in the Hall effect is illustrated by considering a confined stream of free particles, each having a charge e and an initial velocity v_x . A magnetic field in the z direction produces initially a deflection of charges along the y direction. This charge unbalance creates an electric field E_y and the process continues until the force on a moving charge due to the Hall field E_y counterbalances that due to the magnetic field so that further particles of the same velocity and charge* are no longer deflected. A pictorial representation of this is shown in Fig. 1. The magnitude of the Hall field follows at once from Eq. (1), namely

$$E_y = -(1/c)v_x H_z = J_x H_z / nec \text{ (gaussian}^\dagger \text{ units)} \quad (2)$$

FIG. 1. Hall field due to action of magnetic field on positive charge carriers. For example shown, e , J_x and H_z are positive and, therefore, v_x , E_x , and E_y are also. The resultant electric field and the Hall angle are shown at lower left. In the case of electrons, the Hall field is reversed positive J_x .

* If the particles have a *distribution* of velocities, then it is only those particles having a certain "average" velocity, which are undeflected. This point is expanded later.

† In the gaussian system, mechanical quantities are in cgs units, electrical quantities in esu, and magnetic fields in gauss or oersteds. In the *practical* system, mechanical quantities are in cgs units, electrical quantities in volts and coulombs, and magnetic fields in gauss or oersteds. In all equations in this article, except for Eq. (1), conversion from the gaussian system to the practical system is effected by replacing c by unity and replacing H by $H/10^3$, where these quantities explicitly occur. The practical units for R_H are $\text{cm}^3/\text{coulomb}$; those for mobility are $\text{cm}^2/\text{volt-sec}$.

In obtaining the last equality, the electric current density J_x was expressed in terms of the density of charge carriers n by the product nev_x . For *electronic* (i.e., as opposed to *ionic*) conduction in solids, the magnitude of e is the electronic charge (1.6×10^{-19} coulomb, in practical units), and its sign is negative for transport by electrons and positive for transport by holes (deficit electrons). The *Hall coefficient* is defined by the ratio $E_y/J_x H_z$, namely,

$$R_H \equiv E_y/J_x H_z = -1/nec \text{ (gaussian units)} \quad (3)$$

Thus a very simple relation exists in the free-particle example between the Hall coefficient and the charge-carrier density. It is also seen that R_H

is negative for conduction by electrons, positive for conduction by holes. Now the electric current density J_x exists by virtue of an applied electric field E_x . With the Hall field present, the *resultant* electric field in a solid† lies at some angle θ to the x axis. This angle is called the Hall angle, namely

$$\theta \equiv \tan^{-1} E_y/E_x \quad (4)$$

Thus the Hall effect may be described as a rotation of the electric field. At zero Hall field, the equipotential lines are perpendicular to J , but when the Hall field appears, they are oblique, so that a Hall voltage exists across the specimen in a direction normal to the current. The rotation aspect is also brought out by considering the components of the *conductivity tensor*, which relate electric current densities and fields. For the boundary condition that $J_z = 0$, we may write

$$\begin{aligned} J_x &= \sigma_{xx}E_x + \sigma_{xy}E_y \\ J_z &= 0, H = H_z \quad (5) \\ J_y &= -\sigma_{xy}E_x + \sigma_{xx}E_y \end{aligned}$$

Equations (5) hold for media of sufficient symmetry* that $\sigma_{xx} = \sigma_{yy}$ and that $\sigma_{xz} = \sigma_{yz} = \sigma_{zx} = \sigma_{zy} = 0$. The latter insures that E_z vanish when J_z is zero. Since the boundary conditions for Hall effect require that J_y vanish, Eqs. (4) and (5) yield the following result for the off-diagonal elements σ_{xy} :

$$\sigma_{xy} = \sigma_{xx} \tan \theta \quad (6)$$

The inverse of the conductivity tensor is the *resistivity tensor*, which relates E to J . A general definition of the Hall effect involves relating it to the antisymmetric†† components of the resistivity tensor. This leads to the vector equation

$$E = R_H H \times J \text{ (gaussian units)} \quad (7)$$

The identity in the first part of Eq. (3) is recognized as a special case of Eq. (7).

Application to Real Solids. In a real solid, the idealized free particle treatment no longer applies, and it must be replaced by a theory that takes into account the distribution of velocities and the interactions of the charge carriers with impurities, defects, and lattice thermal vibrations of the solid—i.e., the *scattering*—as well as the *band structure* of the solid. The latter consideration relates to the fact that the charge carriers in the solid are not free but exist in a potential energy

field having the periodicity of the lattice. As a result of these constraints, only certain energy states, or *bands*, are allowed for the charge carriers. In addition, the relationship between the energy and velocity of the carriers is not the simple $\frac{1}{2}mv^2$ of the free electron, but is more complex. As an approximation, one frequently characterizes the charge carriers by an *effective mass*, m^* . Taking into account most of the complexities mentioned above, one still obtains an expression similar to Eq. (3), namely

$$R_H = r/nec \text{ (gaussian units)} \quad (8)$$

The *Hall coefficient factor*, r , actually depends on the nature of the scattering, the band structure, the magnetic field strength, and on the statistics characterizing the distribution of velocities of the carriers. Fortunately it depends weakly on these factors, and its value is usually within, say, 50 per cent of unity.

An important attribute of charge carriers is their mobility, i.e., their drift velocity per unit electric field. The conductivity mobility μ is related to the conductivity σ by

$$\mu = \sigma/nec \quad (9)$$

It is also customary to define a *Hall mobility* μ_H for conduction by a single type of charge carrier by the relation

$$\mu_H H/c = \tan \theta, \text{ or } \mu_H = R_H \sigma c \text{ (gaussian units)} \quad (10)$$

With the use of Eqs. (8) and (9), it can be seen that the ratio of Hall and conductivity mobilities is precisely the Hall coefficient factor. It follows that the Hall angle is proportional to μ and H .

When transport by two or more kinds of charge carriers occurs, Eq. (8) is not applicable, and one must return to the general relations of Eq. (5). For conduction by electrons and holes (of respective densities n , p), the *weak-field* Hall coefficient can be written in the form

$$R_H = -(r_e \mu_e^2 n - r_h \mu_h^2 p) / [e]c(\mu_e n + \mu_h p)^2 \quad (11)$$

where $|e|$, μ_e , etc., are positive. We note that the charge-carrier densities are now weighted by the mobilities μ_e , μ_h . There are also Hall coefficient factors for each carrier. For arbitrary H , the terms involve field-dependent factors.

Analysis of Hall-effect data is one of the most widely used techniques for studying conduction mechanisms in solids, especially semiconductors. For the single-carrier case, one readily obtains carrier concentrations and mobilities, and it is usually of interest to study these as functions of temperature. This can supply information on the predominant charge-carrier scattering mechanisms and on activation energies, i.e., the energies necessary to excite carriers from impurity levels into the conduction band. Where two or more carriers are present, the analysis is more complicated [cf. Eq. (11)], but much information can

† Although the Hall effect can be discussed for any constrained electron gas, we shall, for simplicity, talk about a solid conductor.

* Isotropic media, e.g., or cubic systems with coordinate axes along cube axes.

†† These components are defined by the condition that $\rho_{ik} = -\rho_{ki}$, where the ρ_{ik} [cf. Eq. (5)] are defined by $E_i = \sum_{k=1}^3 \rho_{ik} J_k$, $1 = x, 2 = y, 3 = z$.

be obtained from studies of the temperature and magnetic field dependencies.

Unlike, for example, the magnetoresistance, the Hall effect is a first-order phenomenon. At weak magnetic fields, it depends linearly on H , and it does not vanish in isotropic solids if all the carriers have essentially the same velocity or if the scattering is characterized by a relaxation time which is independent of the carrier energy. The Hall effect forms the basis of a number of devices used in isolating circuits, transducers, multipliers, converters, rectifiers, and gaussmeters (for measurement of magnetic fields).

Experimental Determination. A number of techniques are available, the most direct being to measure, by means of a potentiometer or other high-impedance device, the Hall voltage V_H across a parallelepiped in a direction normal to both H and J . The Hall coefficient follows from Equation (3) or (7):

$$R_H = 10^8 V_H t / IH \text{ (practical units)} \quad (12)$$

where t is the thickness of the specimen and I is the total current. The arrangement is shown in Fig. 2. Since V_H may be the order of microvolts, extreme care must be taken to avoid extraneous voltages. An example is the misalignment voltage, caused by probes 3 and 4 not being on an equipotential plane when $H = 0$. This may be eliminated by taking measurements for opposite directions of H and taking half the difference, inasmuch as $V_H(H)$ is odd in H . Alternatively, one can adjust the position of the Hall probes for a null reading with $H = 0$. Other techniques involve use of resistances with sliding contacts suitably attached to the specimen. Other spurious voltages can arise from temperature gradients and resulting thermoelectric or thermomagnetic emf's (see following section). Some of these can be eliminated by taking appropriate averages among measurements for reversed polarities of I and direction of H . It is usually desirable to maintain good thermal contact between all points of the specimen and a constant-temperature bath. Although it is possible to analyze *adiabatic* Hall

data (no heat flow to or from the specimen during measurement), *isothermal* data are preferred because of the simplicity of the equations. All of the relations in this article are for isothermal conditions. Errors in measurement can also result from a shorting of the Hall voltage, especially by the end contacts. With regard to the latter, the error is essentially negligible if the length-to-width ratio of the specimen is about 4 or more, and the Hall probes are near the center.

Related Effects. A widely-studied galvanomagnetic effect is *transverse magnetoresistance*, usually written $\Delta\rho/\rho_0$. This phenomenon can be illustrated by the pictorial scheme in Fig. 1. If a charge carrier is deflected by the Lorentz force so as to traverse a longer path, it will contribute less to the conductivity, and there will be a positive magnetoresistance. It was noted, however, that if all charge carriers have the same velocity, none will be deflected since the Hall field cancels the $\mathbf{v} \times \mathbf{H}$ force. This is the case in an isotropic metal, where the velocity of all the electrons is essentially the Fermi velocity. It is also true for electron scattering mechanisms described by a relaxation time which does not depend on energy. In these cases—assuming, of course, a single type of carrier—there is no magnetoresistance. If, however, there is a distribution of electron velocities—as in a semiconductor—then it is clear that only those electrons of a certain "average" velocity will be undeflected. The remaining carriers having velocities either larger or smaller than the "average" will be deflected and will traverse longer paths, thus increasing the resistance of the conductor. A similar situation obtains if more than one type of carrier is present. It is also apparent that any mechanism which shorts out the Hall voltage—e.g., special geometry, shorting contacts, inhomogeneities in the specimen—will increase the magnetoresistance.

For the reasons discussed and the fact that $\Delta\rho/\rho_0$ varies as H^2 in weak fields, magnetoresistance is a second-order effect. It tends to saturate in strong magnetic fields, unless there is a disturbance of the Hall field as mentioned above.

FIG. 2. Arrangement of contacts for measurement of Hall coefficient and related effects. Hall probes are 3 and 4. Probes 2 and 6 are for resistivity and magnetoresistance. Probes 1 and 5 allow a check of the uniformity of the specimen. For Hall effect and transverse magnetoresistance, the magnetic field is in the direction of the thickness t ; for longitudinal magnetoresistance, it is along l . To avoid disturbances due to contact shorting, all probes should be at a distance of at least $2w$ from the end contacts.

Magnetoresistance is even in H , and it is related to the *symmetric* components of the resistivity tensor, i.e., those for which $\rho_{ik} = \rho_{ki}$ [cf. footnote on p. 304]. It can be measured with the geometry shown in Fig. 2 by maintaining the current constant and determining the potential difference between probes 1 and 5 or 2 and 6 as a function of magnetic field. Magnetoresistance data can supply information on charge-carrier scattering and band structure. In the latter case, if anisotropy exists, it is useful to obtain data for different crystallographic directions. There is also a *longitudinal* magnetoresistance, measured when H is parallel to J . This effect vanishes in isotropic solids, and its presence indicates anisotropy in scattering or band structure, or inhomogeneities in the specimen.

By shorting the Hall field or by choosing a disk geometry so that such a field does not exist, one obtains a "magnetoresistance" (more strictly, a *magnetoconductivity*) which does not saturate. This is called the Corbino magnetoresistance or Corbino effect, after O. M. Corbino who studied circulating secondary currents in a "Corbino" disk carrying a primary radial electric current in a magnetic field.

There are a number of thermal effects in a magnetic field, which can produce transverse voltages or temperature gradients. These result from the velocity separation of charge carriers by the Lorentz force—the energetic ones going to one side, the slower ones going to the other. Temperature gradients are produced, and also electric fields. In the Righi-Leduc effect a longitudinal temperature gradient produces a transverse temperature gradient (thermal analog of the Hall effect); in the Nernst effect, it produces a transverse electric field. In the Ettinghausen effect, a longitudinal electric current produces a transverse temperature gradient. This latter effect, if large, can disturb the Hall field since the potential probes and leads are seldom made of the same material as the specimen. Therefore the Ettinghausen temperature gradient can produce a thermoelectric voltage which adds to the Hall voltage.

HEALTH PHYSICS*

Health physics is the profession that is concerned solely with the protection of man from the damaging effects of ionizing radiation. It attempts to understand the action of radiation on man and his environment, to establish appropriate limits for exposure to radiation, and to devise appropriate methods for detection, measurement and control of radiation exposure. Although this profession is relatively new, man's awareness and concern for the harmful effects of ionizing radiation are not of recent origin. Perhaps the earliest record of damage to man from ionizing radiation dates back to about 1500 when the high incidence of lung diseases was recognized among the Schneeberg miners of Saxony and the Joachimsthal miners of Bohemia. In 1879 Herting and Hess performed the first autopsies on these miners and reported malignant growths in the lungs; however, the cause of these malignancies was not understood until after 1896 when Roentgen first announced his discovery of x-rays and Becquerel reported the discovery of radiation due to uranium. Even during the first year following the discovery of x- and γ -radiation, many things were learned about both the harmful and useful characteristics of this new source of energy. Grubbé, a manufacturer of Crookes tubes in Chicago, Illinois, was using his equipment to study the fluorescence of chemicals even before the public press on January 4, 1896, heralded Roentgen's discovery of x-rays. During January, 1896, he first noticed an erythema on the back of his hand and later the formation of a blister with skin desquamation and epilation. His hand was sufficiently painful that he sought medical aid on January 27, 1896. Realizing from first-hand experience the destructive power of x-rays, Grubbé on January 29, 1896, treated a patient for carcinoma of the breast with his Crookes tube. Not only was this treatment significant because it was one of the earliest - if not the first—therapeutic uses of ionizing radiation, but it is noteworthy that he acted as one of the first health physicists when he used lead as a shield to protect the rest of the body of the patient. Even Becquerel and Madame Curie learned from first-hand experience the need for radiation protection when they received skin

* Work sponsored by the U. S. Atomic Energy Commission under contract with the Union Carbide Corporation.

burns from the careless handling of radium (see RADIOACTIVITY).

S. Russ in 1915 made a comprehensive series of recommendations for radiation protection to the British Roentgen Society, and if these recommendations had been heeded, many of the early radiation fatalities might have been averted. It was not until 1928, when the International Commission on Radiological Protection was formed and published the first set of recommendations for radiation protection, that there began to be widespread interest and concern for this problem. In the following year the National Council on Radiation Protection was formed and it has set the standards in the United States.

Beginning at the time of the First World War and continuing until about 1930, there were many unfortunate exposures to radium. Some of these were the result of therapeutic injections of radium, the drinking of radium and radiothorium water, and occupational exposures of radium chemists. During this period, radium was considered to be a useful therapeutic agent, and as a result it was administered by physicians in the United States to hundreds of patients. In some cases it was taken as a general tonic, and in others it was given as a curative agent for hypertension, anemia, arthritis, and many other human ailments—even for insanity.

By far the most serious exposures were to young women engaged in the radium dial painting industry. Some of these women ingested relatively large quantities of radium as a consequence of tipping brushes with their lips as they applied radium paint on the dials of clocks and watches. The total number of radium dial painters and others who took radium by mouth or injection and, as a result, died with readily detectable symptoms of radiation damage is not known. The first recorded fatality due to radium-induced cancer, resulting from exposure in the radium dial industry, was in 1925, and since that time histories of over 50 such cases have been recorded and studied in the United States.

In 1942–43 there was begun at the University of Chicago a program to explore the possibility of assembling a critical mass of natural uranium in such a way that a "pile" or NUCLEAR REACTOR could be operated for the production of the new element plutonium to be used in atomic weapons. A. H. Compton, the director, and his associates debated the wisdom of proceeding with this project because they realized that in a single large reactor there would be produced ionizing radiation equivalent to that from thousands of tons of radium. Yet all the radium that had been available to man throughout the world only amounted to about two pounds, and these men were acutely aware of the extensive suffering and death that had resulted from its misuse. They decided to call together a rather unique group of scientists to evaluate these health problems, to develop new instruments, equipment, and techniques and to establish radiation standards for the protection of nuclear energy workers. The group assembled was concerned with the *health*

of the workers and consisted mostly of *physicists*; hence, they were called *health physicists*. E. O. Wollan was the leader and the other senior members were H. M. Parker, C. C. Gamertsfelder, K. Z. Morgan, R. R. Coveyou, J. C. Hart, L. A. Pardue, and O. G. Landsverk. Thus in 1942–43 health physics had its beginning at the University of Chicago. Although prior to this time many early pioneers such as S. Russ (England), L. S. Taylor (United States), G. Failla (United States), A. Mutscheller (Germany) and R. Sievert (Sweden)—to name only a few—had devoted considerable attention to the radiation protection problem, it was not until the advent of health physics that a professional group was organized with this as its sole objective.

As the nuclear energy programs expanded, large laboratories were established to carry on the program at Oak Ridge, Los Alamos, Hanford, Berkeley, Brookhaven, Savannah River, etc., and as the need for health physicists was recognized beyond nuclear energy programs and in private industry, hospitals, military organizations, state and federal agencies of public health and in colleges and universities, the profession of health physics grew and expanded very rapidly so that today (1965) it is estimated there are about 5000 health physicists in the world. In 1956 the Health Physics Society was organized which now has a membership of over 2500 in 43 countries. This Society publishes the journal, *Health Physics*. In 1959 the American Board of Health Physics was formed for the certification of persons whose technical competence and judgment qualify them to be responsible for handling major problems of radiation exposure and or contamination control.

There are three principal areas in which health physicists are employed—education and training, applied activities, and research—and these three areas will be discussed below.

In the early period, health physicists were scientists who had to develop their own competence during employment on the various atomic energy programs. In 1948 AEC Health Physics Fellowship programs were established, first at Oak Ridge National Laboratory and later at Vanderbilt University, University of Rochester, University of California, University of Washington, Harvard University, University of Kansas, University of Michigan, University of Puerto Rico, University of Tennessee and at Texas A & M. By 1964 a total of over 700 students had been awarded these Fellowships, and this program has become the principal source of senior health physicists, having produced approximately 300 at the masters level, 70 with Ph.D. degrees and over 350 with graduate training but without advanced degrees. Although most of the early health physicists began as physicists, there is today a need for health physicists with many different backgrounds, e.g., physics, biology, chemistry, mathematics, engineering, etc. In the AEC Health Physics Fellowship program the student meets all the usual Ph.D. requirements of courses, research and thesis in one of these major departments, and at the

same time, he meets additional requirements such as special courses and summer work at one of the National Laboratories where he is given practical experience in health physics. Likewise, some of the graduate programs of the U.S. Public Health Service have been, in more recent years, providing training in health physics. In spite of the various opportunities for education and training in health physics, the supply has not kept pace with the demand because of the rapid growth of this new profession.

In addition to the above-mentioned graduate programs in health physics, there are education and training programs at all operating levels. These programs are important because the success of health physics can be measured, to a considerable degree, in terms of how well plant managers, supervisors, scientists, engineers, technicians and operations personnel are made to realize their responsibility for protecting themselves and their associates from radiation damage. They must be ever aware that to some degree all radiation exposure is harmful and no unnecessary exposure may be permitted unless it can be balanced by benefits of equal value. At the same time they must be made to respect ionizing radiation—not fear it.

The duties of the health physicist in applied operations are very diverse and differ considerably from place to place, depending upon the size and nature of the operation. For example, the health physicist in a reactor operation would have duties quite different from those of the health physicist associated with an accelerator program or the health physicist connected with a state public health organization charged with the survey of medical x-ray equipment. A few typical applied health physics activities may be summarized as follows:

- (1) Aid in the selection of suitable locations for buildings in which radioactive materials are to be produced or used, and conduct pre-operation background surveys.

- (2) Offer advice in the design of laboratories, hoods, remote control equipment, radiation shields, etc.

- (3) Provide personnel monitoring meters for radiation dosimetry to all persons subject to radiation exposure and read these meters frequently; make thyroid counts, breath measurements, urine and feces analyses; check body with scanners and total body counters and conduct other tests to aid in estimating how much (if any) radioactive material is fixed in the body; and maintain accurate records of the accumulated dose from each type of ionizing radiation received by each individual for his protection and for the protection of the employer.

- (4) Make frequent surveys of all accessible reactor areas, radioactive sources, x-ray equipment, high voltage accelerators, chemistry and physics laboratories, metallurgical shops, and other working areas where radiation exposure is possible.

- (5) Advise scientists, supervisors and research directors of all radiation exposure hazards, of

permissible working time in a given area, and of radiation protection measures and techniques (e.g., protective clothing, shields, remote control equipment) and aid supervision in the solution of new radiation problems as they develop.

- (6) Make frequent surveys of all radioactive waste discharged beyond the area of immediate control, maintain accurate records of the level of this radioactivity in the air, water, soil, vegetation, milk, etc., and advise management of remedial measures as they are needed.

- (7) Aid in all emergency operations where there are associated radiation hazards.

- (8) Purchase and maintain in working order and in proper calibration suitable health physics survey and monitoring instruments which are used as aids in the protection of personnel from radiation damage.

- (9) Prepare operations manuals on "Rules and Procedures Governing Radiation Exposure."

- (10) Assist in radiation protection problems related to civil defense, weapons fallout, the use of nuclear devices for excavation of canals and harbors, space radiation, etc.

Health physics research ranges from the applied and engineering programs to very basic studies. It is a working together of scientists of many disciplines—physicists, chemists, biologists, engineers, geologists, mathematicians—all studying the effects of ionizing radiation on man and on his environment. In these studies, they are working at all levels—nuclear, atomic, molecular, plasma, gas, solid, liquid, cell, animal, and the ecosystem. In this research program, radiation ecologists are studying the effects of low levels of radiation exposure on the environment. Some essential organisms in the environment are known to concentrate radioactive waste by a factor of 10,000 or more, and the health physicist must determine the importance of the indirect damage of ionizing radiation to man's environment as well as its direct effects. Internal dose studies are under way by researchers in health physics, studies which have led to the publication of the official handbooks on maximum permissible concentration of the various radionuclides in food, water, and air. These handbooks are issued by the National Council on Radiation Protection and the International Commission on Radiological Protection. They are under constant revision by the health physicist as more reliable and detailed information becomes available. Biologists in health physics are studying the uptake distribution and elimination of radionuclides which are taken into animals and man by the several modes of intake—ingestion, inhalation and skin penetration. Engineers in health physics are exploring and demonstrating new methods for the disposal of radioactive waste in deep wells thousands of feet below the earth's surface and in salt mines. They are studying the seepage rates of radionuclides into various soil formations, its slow dissipation from packages of radioactive waste deposited on the ocean floor, and the dilution of airborne radioactive waste as it is discharged from stacks under varying meteorological

conditions. The physicists in health physics are making basic studies of the various energy exchanges that take place in matter when it is exposed to ionizing radiation. This information aids in the development of better radiation detection systems and leads to an understanding of the true meaning and consequence of radiation exposure. When high energy radiation (in the MeV or keV region) strikes living matter, there are innumerable, complex energy exchanges that take place as the entropy of the system increases. An understanding of the many low energy transitions is basic to a proper interpretation of the effects of ionizing radiation on man. Health physicists are working toward the ultimate goal of developing a coherent theory of radiation damage. Only when such a theory is available can they have complete understanding and confidence in the many extrapolations to man of the effects of ionizing radiation on animals. Such information is essential in developing reliable radiation protection standards and measures that are enforced by the applied health physicist.

Health physics continues to grow as a most interesting and challenging profession for scientists of many backgrounds. The success of these programs is attested by the fact that ionizing radiation with unparalleled potential for radiation hazards has expanded in its use and applications into almost every area of human endeavor and yet the nuclear energy industry has become one of the safest of all industries.

HEARING

The role of the sense organ of hearing is to code acoustic disturbances into neural signals suitable for transmission to the brain. The study of this process necessarily involves anatomy and physiology of the ear, the nature of auditory pathways and central nervous system activity in hearing, properties of acoustic signals that elicit auditory responses, and observed phenomena of auditory behavior. These aspects serve to define and delineate areas for investigations of hearing and are the topics of discussion for this article.

In this approach to hearing, questions are asked about the structure of the system, how the system functions, and the relationships between inputs and outputs of the system. These three kinds of data—morphological, physiological, and psychological—need to be compared and correlated for a full understanding of hearing. It is important, however, that these three frames of reference be kept separate and not be confused. Although physiological functions may correspond in a general way to anatomical sequences, several physiological functions may occur in the same anatomical structure or a single function may require several anatomical units. In a similar manner, psychological functions cannot usually

be identified with specific physiological functions, and it is recognized that the central nervous system, as well as the auditory system, is involved in any auditory response. The correlations between and knowledge about structure and functions are best developed for peripheral, rather than central, parts of the auditory system because the ear is more accessible for examination and study than are the more central parts of the auditory system.

Traditional theories of hearing have been largely concerned with pitch perception or loudness of pure tones. Recently, there has been an increased awareness that any comprehensive theory of hearing needs to encompass various experimental phenomena of hearing. In this regard, increased attention has been given to auditory processing of complex signals, to the examination of binaural inputs to the system, and to the study of pathological hearing conditions.

When the structure of the ear is examined, it is convenient to consider the external, middle and inner ear separately. From a functional point of view, the ear may be divided into an outer and inner part. The outer is concerned with the transformation of acoustic energy into mechanical energy and the inner with the transduction of mechanical energy into neural impulses. The auricle and external auditory meatus constitute the external ear. The meatus is an irregularly shaped tube approximately 27 mm long with a diameter of about 7 mm, terminated by the tympanic membrane. The ear canal is an acoustic resonator, and frequencies in the range of 3000 to 4000 cps are increased in pressure at the ear drum as compared to the pressure at the entrance to the canal. The ear drum is in a protected position at the end of the canal, and humidity and temperature conditions at the drum are relatively independent of those external to the ear.

The middle ear is an irregular, air-filled space in the petrous portion of the temporal bone. The three ossicles of the middle ear—the malleus, the incus, and the stapes—provide mechanical linkage between the tympanic membrane and the fenestra vestibuli, an opening in the vestibule of the inner ear commonly known as the oval window. The handle of the malleus attaches to the tympanic membrane, and the footplate of the stapes attaches to the oval window. Two important functions are provided by the middle ear. The first is to amplify and deliver sound vibrations from the drum to the inner ear, and the second is that of protecting the inner ear from very loud sounds. The amplification of sound waves is accomplished by apparent lever action of the ossicles that produces a greater force at the oval window than the force at the drum and because of the gain in force that results from the relationship between the larger drum area to the smaller stapedial footplate area. The area of the drum is approximately 25 times that of the oval window. The amplification gain of these two factors is approximately 25 db. The effectiveness of the middle ear action in increasing hearing sensitivity is evidenced in middle ear pathologies where the ossicular chain is disrupted. A hearing

loss of 25 db or more occurs. The second function of the middle ear, that of protecting the inner ear from loud sounds, is accomplished by reflex action of the middle ear musculature, the tensor tympani, and the stapedius. The action of the muscles is to retract the ear drum, draw the stapes away from the oval window, and change ossicle vibrations in such a way as to decrease the transmitted pressure. Latency of muscle contraction and possible muscle fatigue limit protection of the inner ear by these mechanisms. Middle ear air pressure is equalized by virtue of the Eustachian tube which connects the middle ear and the nasopharynx. The pressure equalization is necessary for normal ear drum movement.

The inner ear is a system of cavities in the dense petrous portion of the temporal bone. One of the cavities is the cochlea, a bony labyrinth that is approximately 35 mm in length coiled around a central core for two and three-quarters turns. The spiral-shaped cochlea is divided into three ducts, two bony and one membranous. The upper bony duct, the scala vestibuli and the lower bony duct, the scala tympani, are separated from each other by a membranous labyrinth, the cochlear duct. The cochlear duct is bound on top by Reissner's membrane and is bound below by the basilar membrane. The cochlear duct is filled with a viscous fluid called endolymph, and the duct is surrounded by a fluid called perilymph that has about twice the viscosity of water. The scala vestibuli and the scala tympani join at the apical end of the cochlea at a passage called the helicotrema. The scala tympani terminates at the basal end at the round window, a membrane-covered opening into the middle ear. The scala vestibuli is continuous with the vestibule; the oval window opens into the vestibule. Vibrations at the footplate of the stapes are transmitted into the fluid adjacent to the oval window. Vibration of the stapes and resultant disturbances in cochlear fluids results in movement of the basilar membrane. The cochlear duct contains the sensory receptors, specifically the organ of Corti, which lies upon the basilar membrane. There are about 25 000 hair cells; one end of each rests on the basilar membrane. The other ends of the hair cells are the cilia, very fine hairline processes, which make contact with the tectorial membrane, a membrane that overlaps the organ of Corti and that functionally behaves as if it were hinged at the cochlear wall. There are three rows of outer, and one row of inner, hair cells along most of the length of the basilar membrane. When vibrations are introduced into the inner ear and cause displacement of the basilar membrane, a shearing of the action of the cilia occurs that results in neural activity. It is assumed that amplification occurs in the inner ear in that small pressures on the basilar membrane result in a shearing force of considerably greater magnitude that distorts the hair cells. The result is increased sensitivity of the hearing system. Physical properties of the cochlea are such that different frequencies tend to localize at different points along the basilar membrane. The basilar membrane is narrowest and stiffest at the basal end,

and most lax and widest at the apical end of the cochlea. High-frequency sounds result in the greatest disturbances near the basal end, and low-frequency sounds tend to localize near the apical end. When the role of the cochlea in pitch and loudness analyses is considered it is now realized that more is involved in pitch perception than the place of localization on the basilar membrane, although the particular neural fibers involved are probably relevant. Loudness is probably related to the total number of neural impulses per unit time.

The auditory pathways provide for the neural impulses from the ear to be transmitted to the cerebral centers of the auditory cortex. Processing of the neural signals probably occurs at synaptic connections as well as in the cortex. The cell bodies of the receptor neurons are located in the spiral ganglion. Neurons of the auditory nerve make synaptic connections with the hair cells of the cochlea. Nerve fibers typically innervate many hair cells, and more than one nerve fiber may make a connection with the same hair cell. There is recent evidence to indicate that there are also descending neural pathways as well as ascending ones. The central nervous system may thus be involved in auditory processing at the cochlea. Spiral ganglion axons make synaptic connections with cells of the central nervous system at the cochlear nucleus. At this point, there is interconnection between the pathways for the two ears. Other synaptic stations between this point and the auditory cortex include the inferior colliculus and the medial geniculate body. Evidence from pathological auditory systems is of particular interest with respect to the auditory pathways. An impaired cochlea, for example, may result in a better than normal response to small amplitude changes in a sound. A lesion of the VIIIth Nerve is frequently manifested by a rapid decrease in the ability to respond under sustained stimulation. The ability to process speech is markedly affected when there is an involvement of the lower central nervous system. Cortical involvement does not affect usual speech or pure tone inputs.

Sound involves a disturbance in the air that is a forward and backward, rarefaction and compression, movement of air particles. The unit of force usually used in acoustics is the dyne. Sound pressure is frequently expressed in dynes per square centimeter. Intensities of sounds are usually measured on a decibel scale, a logarithmic ratio scale. The tremendous loudness range of the ear is exemplified by the fact that the most intense sound that can be tolerated is a million million times greater in intensity than a sound that is just audible. This is a range of approximately 120 db. The frequency range of hearing is frequently given as 16 to 20 000 cps. The ear is most sensitive in the middle frequency range of 1000 to 6000 cps. In terms of discrimination of frequency and intensity, it is possible for about 1400 pitches and 280 intensity levels to be distinguished.

The truly phenomenal aspects of hearing can be observed in such behavior as localization of sounds, speech perception and particularly the

understanding of one voice in the noisy environment of many, and the recognition of acoustic events that only last a few milliseconds. It is these and other behavioral phenomena that need to be accounted for in theories of hearing.

HEAT

Heat vs Temperature. Heat is the imponderable but not intangible agency whose addition to or removal from a physical system is the cause of thermal changes of various types. These include rise and fall of temperature, changes in length and volume, changes of physical states such as melting, evaporation and the like.

During the eighteenth century heat was assumed to be a subtle fluid called *caloric*, filling the interstices between the ultimate particles of matter and, under conditions of isolation from the surroundings, known to satisfy a conservation law. The production of heat by friction as well as its disappearance during the performance of external mechanical work established its essential physical nature as another form of *energy* and led to the overthrow of the caloric theory. Nevertheless, we still speak of the *flow* of heat as though it were a fluid and have retained the methods of measuring the *quantity of heat* originally devised by the upholders of the caloric view.

Our direct knowledge of heat is provided by the sensation of hotness and coldness when we come in contact with various physical bodies. It is possible to arrange a set of bodies in a sequence such that A feels hotter than B, B hotter

than C, etc. We say that A has a higher *temperature* than B, B a higher one than C, and so on. Of course our sensations are qualitative and are considerably influenced by the thermal conductivity of the body we touch. Thus, on a frosty morning, the head of an ax being metal feels considerably colder than the wooden handle though the two are presumably at the same temperature. To obtain a continuous and reproducible physical scale of temperature, various types of thermometers have been devised of which the mercury-in-glass or colored-alcohol-in-glass are familiar examples. The two temperature scales in common use are the Fahrenheit scale and the Celsius scale. The first assigns values of 32° and 212° to the normal freezing and boiling points of pure water, respectively, and divides this interval into 180 equal sub-intervals or degrees. The Celsius, formerly called the Centigrade, scale assigns the respective values of 0° and 100° to the above fixed points; the standard interval is then divided into 100 equal degrees.

Temperature changes being produced by the addition or subtraction of heat from a body, temperature itself may be regarded as a measure of the concentration or *intensity* of heat. In general, the more heat we add to a given body the more its temperature rises.

Measurement of Heat. Since heat is imponderable and not directly observable, it is necessary to measure the size of a given quantity of heat by its effect on another body. If this effect is the production of a rise in temperature from some initial temperature, t_1 , to a final temperature, t_2 , then the rise ($t_2 - t_1$) is found to vary inversely with the mass of the test body. It is thus natural therefore, following the calorists, to regard the quantity of heat, say Q , as determined by the product of m and ($t_2 - t_1$). Thus we say

$$Q \text{ is proportional to } m \cdot (t_2 - t_1)$$

To make this statement into an equation we write

$$Q = \text{constant} \cdot m \cdot (t_2 - t_1) \quad (1)$$

where the constant of proportionality depends on the substance, being large for some materials and small for others. This constant for water, for example, is about 33 times as great as for lead; water is said therefore to have a greater *heat capacity* than lead. Notice that the constant in Eq. (1) actually gives the numerical value of Q which is required to warm a unit mass of the substance through a temperature interval of exactly 1°. This constant is accordingly called the *specific heat capacity* (usually abbreviated to *specific heat*) and is indicated by c . Since it is found that the value of the specific heat, particularly for gases, but in principle for all materials, depends on the conditions under which the heat is absorbed, this must be indicated. We thus have c_p and c_v , for example, for the two important cases of absorption at constant pressure and constant volume respectively. Since the former characterizes the common laboratory case of

working under atmospheric pressure, we accordingly rewrite Eq. (1) as

$$Q_p = c_p m(t - t_1) \quad (2)$$

Q_p now measures the heat absorbed under constant pressure, and c_p is the constant pressure specific heat. Since the right side of Eq. (2) contains *three* quantities, a mere choice of a mass unit and a degree unit is insufficient to establish a unit of heat. It is necessary to select some substance as a standard reference body and assign an arbitrary value of, say c_p equal to unity for it. Water is the universal choice for this standard body due not only to its cheapness and ease of purification but also to its large heat capacity.

With the selection of water as the standard with $c_p = 1$, the left side of Eq. (2) clearly becomes of unit value when m and $(t - t_1)$ are each of unit value. In the English system we accordingly have the *British thermal unit* (or Btu) as the heat required to warm 1 pound of pure water through an interval of 1° F. In the metric system, the corresponding unit is the *calorie*, the heat required to warm 1 gram of water 1°C. A large or *kilocalorie* corresponding to 1000 ordinary calories is also frequently used in scientific work.

Specific Heats. Use of Eq. (2) reveals that the values of c_p obtained experimentally depend on the temperature interval used, indicating a dependence of c_p on temperature. Thus if c_p for water were actually unity throughout the 0 to 100°C range, a mass of water at 100°C mixed with an equal mass at 0°C would give a final mixture at exactly 50°C. The actual value is near 50.05°; this difference although small, indicates the need to specify the calorie at some particular temperature. For this purpose, we suppose a system of mass m is warmed from t to $t + \Delta t$ by the addition at constant pressure of an increment of heat ΔQ_p . Then Eq. (2) becomes

$$\Delta Q_p = m \bar{c}_p \Delta t \quad (3)$$

where now \bar{c}_p is an average value of c_p over this interval. Then we define the *instantaneous* heat capacity, c_p at t by the following relation:

$$c_p = \frac{1}{m} \lim_{\Delta t \rightarrow 0} \frac{\Delta Q_p}{\Delta t} = \frac{1}{m} \frac{dQ_p}{dt}$$

i.e., the heat absorbed per unit mass per degree as the interval becomes smaller and smaller without limit. This leads to the differential form of Eq. (3)

$$dQ_p = m c_p dt \quad (4)$$

where dQ_p is the differential heat absorption which produces a differential temperature rise dt in a body of mass m and specific heat c_p .

The standard or 15 calorie is now defined as the rate of absorption of heat per gram per degree at 15°C and in practice is essentially the same as the average calorie over the 1° interval from 14.5 to 15.5°C.

If a mass m of water is warmed from t_1 to t , the integral of Eq. (4) gives for the total heat absorbed in 15 calories

$$\begin{aligned} Q_p &= \int_{t_1}^t dQ_p = m \int_{t_1}^t c_p dt = \\ &= m \left[\int_{0^\circ}^t c_p dt - \int_{0^\circ}^{t_1} c_p dt \right] \quad (5) \end{aligned}$$

where the integral of c_p over the range t_1 to t has been written as the difference of two integrals from a common lower limit of 0°C. If, therefore, we evaluate an integral of the type $\int_0^t c_p dt$ with t varying in 1° steps and arrange these in a table, the right side of Eq. (5) may be evaluated by merely subtracting appropriate entries.

In Fig. 1, the value of c_p in 15° calories per gram per degree is plotted graphically from 0 to 100°C and the integrals on the right of Eq. (5) are represented by appropriate areas under the c_p curve. Thus the integral from 0° to t is hatched with lines sloping up to the right, while that from 0° to t_1 has the lines sloping up to the left. The value of Q_p is then the singly hatched area.

FIG. 1. Specific heat of water vs temperature.

With heat quantities measured in 15° calories, from the observed rise or fall of temperature in known masses of water, the specific heats of various substances, the heats absorbed on melting solids to liquids (heats of fusion), the heats absorbed on passage from the liquid to the vapor state (heats of vaporization), the heats evolved on combination of various substances, and the heats absorbed or evolved in chemical changes are at once determinable (see CALORIMETRY). For the present purpose, Table 1 gives the values of the constant pressure heat capacities of a few typical substances, variations with temperature being disregarded. Notice that c_p although expressed in terms of calories per gram per degree is in fact independent of the system of units since water is the reference body in all systems. Thus the specific heat of water in the English system would be 1 Btu per pound per degree Fahrenheit.

The Mechanical Nature of Heat. The conservation of heat *per se* is observed only for systems involving the performance of no mechanical or electrical work. Count Rumford (ca. 1800) was the first to establish this fact in his famous cannon-boring experiments carried out in the

TABLE I

Substance	State	$c_p(\text{cal/g deg})$
Water	Vapor	0.48
Water	Liquid	1.00
Water	Solid	0.50
Ethyl alcohol	Liquid	.54
Hydrogen	Gas	3.44
Air	Gas	.24
Aluminum	Solid	.22
Iron	Solid	.11
Lead	Solid	.03

arsenal of the Dutchy of Bavaria in Munich. He observed that when his drills became dull, heat was produced in great quantities limited only by the amount of work done against friction. He concluded that the large scale mechanical energy used in overcoming friction could only be converted into the motions of the ultimate particles of matter, a motion not directly observable but detected by our senses as heat. His results were confirmed and extended by the later work of Joule and Helmholtz, in particular, and also provided a more reliable value for the so-called *mechanical equivalent of heat*. This is taken as the amount of mechanical (or electrical) energy which when converted into heat is equivalent to exactly 1 calorie. The presently accepted value for this important constant is 4.185 joules per 15° calorie. Here the joule is the work performed when power is expended at the rate of 1 watt for 1 second. Thus an ordinary 100-watt lamp bulb converts 100 joules of electrical energy to thermal each second; this amounts to 100/4.185 or about 24 calories.

As a result of experiments such as these and a host of others, we are forced to recognize that heat is merely another form of the universal quantity *energy*. Its transformation always occurs at the rate of 4.185 joules per calorie whether heat goes into external work or work is dissipated through friction into heat.

For details of the mechanical interpretations of heat in the case of ideal gases and simple solids see KINETIC THEORY.

HEAT CAPACITY

The heat capacity of any thermodynamic system is

$$C = \frac{\delta q}{dT} \quad (1)$$

where δq is the quantity of heat* required to produce the temperature increment dT . If the system consists of a single substance with definite chemical composition and physical state, C is proportional to the total quantity of matter in the system. The heat capacity of 1 gram is the specific heat, and the heat capacity of one mole is sometimes called the molar heat capacity. Commonly used units of heat capacity include cal mole⁻¹ deg⁻¹, cal g⁻¹ deg⁻¹, and joule mole⁻¹ deg⁻¹.

The heat capacity of a substance depends on the variables that determine its thermodynamic state—e.g., temperature, pressure, electric and magnetic field—and also on the constraints imposed during the absorption of heat. Here we limit consideration to a substance subject to a hydrostatic pressure P and to no other forces. In this case, the thermodynamic state is determined by two variables, usually taken to be temperature and either pressure or molar volume V . The usual constraints for which C is of interest are constant volume and constant pressure, and the symbols C_V and C_P are used for the heat capacities measured under these conditions.

The difference between C_P and C_V is related to other thermodynamic properties by the first law of thermodynamics, which, for processes of interest here, may be written

$$\delta q = dU + P dV = dH - V dP \quad (2)$$

where U is the energy and $H = U + PV$ is the enthalpy. (We write this and all subsequent expressions involving thermodynamic properties for one mole.) From Eqs. (1) and (2), we have

$$C_V = \left(\frac{\partial U}{\partial T} \right)_V \quad (3)$$

and

$$C_P = \left(\frac{\partial U}{\partial T} \right)_P + P \left(\frac{\partial V}{\partial T} \right)_P = \left(\frac{\partial H}{\partial T} \right)_P \quad (4)$$

Subtraction of Eq. (3) from Eq. (4) and substitution of the mathematical relation

$$\left(\frac{\partial U}{\partial T} \right)_P = \left(\frac{\partial U}{\partial T} \right)_V + \left(\frac{\partial U}{\partial V} \right)_T \left(\frac{\partial V}{\partial T} \right)_P \quad (5)$$

gives

$$C_P - C_V = \left[\left(\frac{\partial U}{\partial V} \right)_T + P \right] \left(\frac{\partial V}{\partial T} \right)_P \quad (6)$$

The quantity of heat required to produce a certain temperature increase dT is greater at constant pressure than at constant volume by the sum of the work of expansion in the constant pressure process, $P(\partial V/\partial T)_P dT$, and the increase in internal energy accompanying the expansion, $(\partial U/\partial V)_T(\partial V/\partial T)_P dT$.

An expression for $C_P - C_V$ that is more useful than Eq. (6) is

$$C_P - C_V = TV\alpha^2/\kappa \quad (7)$$

* The symbol δ indicates a differential that is not exact, i.e., not determined by the initial and final thermodynamic states.

which can be obtained from Eq. (6) by introducing a relation based on the second law of thermodynamics,

$$\left(\frac{\partial U}{\partial V}\right)_T + P = T\left(\frac{\partial P}{\partial T}\right)_V$$

the mathematical relation

$$\left(\frac{\partial P}{\partial T}\right)_V = \left(\frac{\partial V}{\partial T}\right)_P / \left(\frac{\partial P}{\partial P}\right)_T$$

and the definition of the coefficients of thermal expansion α and isothermal compressibility κ ,

$$\alpha = \frac{1}{V} \left(\frac{\partial V}{\partial T}\right)_P \quad (8)$$

and

$$\kappa = -\frac{1}{V} \left(\frac{\partial V}{\partial P}\right)_T \quad (9)$$

The subject of the following sections is the relationship of the heat capacities of ideal gases and solids to the energies associated with different degrees of freedom of the constituent particles. The heat capacity of a liquid is more complicated and is not considered here.

Ideal Gases. An ideal gas obeys the equation of state, $PV = RT = NkT$. The gas constant R is 8.314 joule mole⁻¹ deg⁻¹, N is Avogadro's number, and $k = R/N$ is Boltzmann's constant. By Eqs. (7), (8) and (9), $C_P = C_V + R$.

In the application of statistical mechanics to the calculation of C_P or C_V it is convenient to consider first the predictions based on classical statistical principles. The pertinent result of classical statistical mechanics is the principle of equipartition of energy: any term in the energy of a particle proportional to the square of either a coordinate or a momentum contributes an average of $\frac{1}{2}kT$ to U . Since the molecules of an ideal gas have three translational degrees of freedom, each with an associated kinetic energy proportional to the square of a momentum, the expected translational contributions to the energy and heat capacity are $U = \frac{3}{2}NkT = \frac{3}{2}RT$ and, by Eq. (3), $C_V = \frac{3}{2}R$. For monatomic gases this is the only contribution to C_V and this value is in excellent agreement with experiment.

Diatomic molecules can rotate about each of two independent axes perpendicular to the internuclear axis, and the two atoms can vibrate with respect to each other along the internuclear axis. Each of the two rotational degrees of freedom has a kinetic energy proportional to the square of a momentum, and the vibrational degree of freedom has both a kinetic energy proportional to the square of a momentum and a potential energy proportional to the square of a coordinate (the vibration is approximately harmonic). In classical statistical mechanics, C_V is therefore expected to be $\frac{7}{2}R$, but for most diatomic gases at room temperature C_V is close to $\frac{5}{2}R$. This discrepancy, one of the historically important failures of classical theory, is resolved by proper consideration of quantum effects as suggested by Einstein. The allowed energy levels of a harmonic oscillator are

not continuous as in classical mechanics, but are given by

$$\epsilon_n = nh\nu, \text{ with } n = 0, 1, 2, 3, \dots$$

where h is Planck's constant, ν is the natural frequency of the oscillator, and the energies ϵ_n are measured from the lowest level. For the average energy of a single oscillator, quantum statistical mechanics gives

$$\bar{\epsilon} = \frac{h\nu}{e^{h\nu/kT} - 1}$$

Instead of the classical value k , the contribution to C_V is

$$\frac{d\bar{\epsilon}}{dT} = k \frac{\left(\frac{h\nu}{kT}\right)^2 e^{h\nu/kT}}{(e^{h\nu/kT} - 1)^2} \quad (10)$$

This contribution to C_V is negligible for $T \ll 0.1 h\nu/k$ because most of the oscillators remain in the $n = 0$ level, but it increases rapidly near $T \approx h\nu/k$ and approaches the classical value for $T \gg h\nu/k$. For many diatomic molecules, $h\nu/k$ is a few thousand degrees Kelvin or more, and a room-temperature C_V of $\frac{5}{2}R$ can be understood as the sum of the translational and rotational contributions. The details of the temperature dependence predicted by Eq. (10), including the approach of C_V to $\frac{7}{2}R$ at sufficiently high temperatures have been verified experimentally for a number of gases.

In a few cases (H_2 , HD and D_2), diatomic gases exist at temperatures for which kT is comparable to the spacing of the rotational energy levels, and quantum effects can be observed in the rotational contribution to C_V . For H_2 , C_V drops below $\frac{5}{2}R$ as the temperature is reduced below about 300 K, and below 50 K it becomes equal to the $\frac{3}{2}R$ that is characteristic of translation. The translational energy levels of ordinary gases are so closely spaced that quantum effects are never important in the translational heat capacity.

The heat capacity of polyatomic gases can be treated by a straightforward generalization of the foregoing discussion. A molecule with n atoms has three translational degrees of freedom and, if it is nonlinear, three rotational and $3n - 6$ vibrational degrees of freedom. If it is linear, it has two rotational and $3n - 5$ vibrational degrees of freedom.

Solids. For every solid there is a lattice heat capacity associated with vibrations of the atoms. If the interatomic forces are harmonic, the N atoms in one mole of a monatomic solid have $3N$ independent vibrational modes, and the lattice heat capacity is the sum of $3N$ terms given by Eq. (10). Since the spectrum of the $3N$ frequencies of a real solid is complicated and difficult to calculate, an approximation introduced by Debye is widely used. In the Debye model, the vibrational modes are sound waves in an elastic continuum; the boundaries of the solid determine the allowed wavelengths and the sound velocities then determine the frequencies. To limit the number of frequencies to $3N$, the spectrum is cut off at a

maximum frequency $k\Theta_D/h$ where Θ_D , the Debye temperature, is determined by the sound velocities and is typically a few hundred degrees Kelvin. The cutoff corresponds to the fact that in a real crystal, the vibrations have a minimum wavelength comparable to the interatomic distance. The heat capacity is

$$C_V = \frac{12}{5} \pi^4 R \left(\frac{T}{\Theta_D} \right)^3 \quad (11)$$

for $T < \Theta_D/20$, but it increases less rapidly at higher temperatures and approaches the classical limit $3R$ for $T \rightarrow \Theta_D$. The predicted high-temperature limit is in agreement with the empirical rule of Dulong and Petit: for most monatomic solids C_V is approximately $3R$ at room temperature. However, this value is often exceeded at very high temperatures, partly as a consequence of anharmonicity in the interatomic forces. At low temperatures, Eq. (11) is in good agreement with experiment; C_V is found to be proportional to T^3 , although often only at temperatures below $\Theta_D/100$, and Θ_D is given accurately by the sound velocities. This agreement is to be expected because at low temperatures only low-frequency vibrations contribute and these *are* sound waves and therefore treated accurately in the Debye model. At intermediate temperatures, the agreement with experiment is only approximate.

Occasionally the lattice heat capacity of a molecular crystal is represented by the sum of a Debye heat capacity for the vibrations of the N molecules as units and the appropriate number of terms given by Eq. (10) for the intermolecular vibrations.

In metals, there is an electronic heat capacity related to the translational motion of the conduction electrons. The small mass and high density of the electrons make quantum effects important, and Sommerfeld showed that their heat capacity should be proportional to temperature for temperatures below about 10^4 K. This contribution is usually significant below a few degrees Kelvin, where the lattice heat capacity is small, and also at high temperatures, where it contributes to deviations from the rule of Dulong and Petit.

The heat capacities of a number of solids have bumps or peaks superimposed on the smoothly varying lattice and electronic heat capacities. These are usually called anomalies and two distinct types can be recognized. A Schottky anomaly is a smooth bump that arises from a set of energy levels for a single particle. The splitting of the rotational states of magnetic ions by electric fields, and of nuclei by electric or magnetic fields, are examples for which the associated anomalies occur in the ranges 10^{-1} to 10^3 K and 10^{-3} to 10^{-1} K, respectively. Lambda anomalies are sharp peaks produced by cooperative processes involving many particles in a transition from a low-temperature ordered state to a high-temperature disordered state. Examples are: the momentum ordering of ^4He atoms in liquid ^4He at 2.18 K and of electrons in superconductors at temperatures ranging from 10^{-1} to 10^4 K; the

magnetic ordering of ferromagnets and antiferromagnets at temperatures from 10^{-3} to 10^3 K; the spatial ordering of different atoms of an alloy on a superlattice, e.g., β -brass at 750°K; and the rotational disorder in certain molecular crystals e.g., H_2 at 1.5°K.

HEAT TRANSFER

Establishment of thermodynamic equilibrium for a system consisting of a number of media requires that the temperature be locally uniform and time-wise constant. A departure from this condition causes a transfer of energy in the form of heat from locations with high temperature to locations with low temperature. Such an energy transfer occurs very frequently and is encountered in our everyday life as well as in many engineering applications or in scientific experiments. It has, therefore, been known for a long time. The fact that quantitative predictions have become possible in the recent past only is due to the situation that several mechanisms are usually involved and interrelated in such an energy transfer process. They are generally classified as conduction, convection and radiation.

Heat transfer by conduction is that process which transports heat in a medium from one location to another without involvement of any visible movement. It is generally the only or the dominating mode of heat transfer in a solid medium; however, it occurs also in liquids and gases. In such fluids, this energy transport is often augmented when parts of the fluid are in movement and carry energy along. This mechanism of heat transfer is classified as transfer by convection. All media can also release energy in the form of photons (electromagnetic waves). This energy travels in space essentially with the velocity of light until the photons are recaptured by some other atoms, causing in this way heat transfer by radiation. An example of this energy transport is the transfer of heat from the sun to the earth. The three modes of energy transfer mentioned above will be discussed consecutively in the following sections. However, it must be realized that they often occur simultaneously, so that in some cases the total energy transport will be the sum of the contributions of the individual mechanisms. In other cases, such a summation will not lead to the correct result when the individual transport mechanisms mutually interfere.

Conduction. From a microscopic standpoint, thermal conduction refers to energy being handed down from one atom or molecule to the next one. In a liquid or gas, these particles change their position continuously even without visible movement and they transport energy also in this way. From a macroscopic or continuum viewpoint, thermal conduction is quantitatively described by Fourier's equation which states that the heat flux

q per unit time and unit area through an area element arbitrarily located in the medium is proportional to the drop in temperature, $-\text{grad } T$, per unit length in the direction normal to the surface and to a transport property k characteristic of the medium and called thermal conductivity.

$$q = -k \text{ grad } T \quad (1)$$

Predictions for the value of the thermal conductivity k can be made from considerations of the atomic structure. Accurate values, however, require experimentation in which the heat flux q and the temperature gradient $\text{grad } T$ are measured and these values are inserted into Fourier's equation. Figure 1 presents thermal conductivity values for a number of media in a large temperature range. It can be recognized that metals have the largest conductivities and, among those, pure metals have larger values than alloys. Gases, on the other hand, have very low heat conductivity values. Electrically nonconducting solids and liquids are arranged in between. The low thermal conductivity of air is utilized in the development of thermally insulating materials. Such materials, like cork or glass fiber, consist of a solid substance with a very large number of small spaces filled by air. The thermal transport occurs then essentially through the air spaces, and the solid structure only supplies the framework which prevents convective currents. The range of thermal conductivities in Fig. 1 at ambient temperature

extends through 5 powers of 10. This range is still small compared with the range for the electric conductivity of various substances where electric conductors have values which are larger by 25 powers of 10 than electric insulators. As a consequence of this fact, it is much easier to channel electricity along a desired path than to do so with heat, a fact which accounts for the difficulty in accurate experimentation in the field of heat transfer.

Fourier's equation can be used together with a statement on energy conservation to derive a differential equation describing the temperature field in a medium. Fourier was the first one to develop this equation and to devise means for its solution. In vector notation, this equation is

$$\rho c \frac{\partial T}{\partial t} = \nabla(k \nabla T) \quad (2)$$

where ρ is the density, c is the specific heat, t is time, ∇ is the Nabla operator. The temperature field in a substance can either change in time (unsteady state) or it can be independent of time (steady state, $\partial T / \partial t = 0$). For a steady-state situation, the temperature field depends primarily on the geometry of the body involved and on the boundary conditions. The simplest case of a steady state temperature field is the one in a plane wall with temperatures which are uniform on each surface, however different at the two surfaces. The temperature in the wall then changes linearly in the direction of the surface normal as long as the variation of the thermal conductivity in the temperature range involved can be neglected. For an unsteady process, the capacity of the medium to store energy enters the energy conservation equation; correspondingly, the specific heat of the material and its density become factors for the conduction process, as well as the thermal conductivity. A combination of these properties, defined as the ratio of the thermal conductivity to the product of specific heat and density, called

thermal diffusivity $\left(\frac{k}{\rho c}\right)$, then determines how fast existing temperature differences in a medium equalize in time. It is found that metals and gases have thermal diffusivity values which are approximately equal in magnitude and considerably higher than thermal diffusivities of liquid and solid nonconductors. This means that temperature differences equalize much faster in metals and gases than in other substances.

Various other physical processes lead in their mathematical description to equations of the same form as Eq. (2), especially in its steady-state form. Such processes are, for instance, the conduction of electricity in a conductor or the shape of a thin membrane stretched over a curved boundary. This situation has led to the development of analogies (electric analogy, soap film analogy) to heat conduction processes which are useful because they often offer the advantage of simpler experimentation.

FIG. 1.

Convection. It has been mentioned before that in fluids, energy is often transported by convection. In such a situation, conduction takes care of the transport of heat from one stream tube to another and is the dominating mode of transfer near solid walls. Convection transports heat along the stream lines and is dominating in the main body of the fluid where the velocities are large. In many situations, the flow is turbulent; this means that unsteady mixing motions are superimposed on the mean flow. These mixing motions contribute also to a transport of heat between stream tubes, a process which can be thought of as being described by an "effective" conductivity which often has values by several powers of ten larger than the actual conductivity of the fluid.

The movement of the fluid may be generated by means external to the heat transfer process as by fans, blowers, or pumps. It may also be created by density differences connected with the heat transfer process itself. The first mode is called *forced convection*, the second one *natural or free convection*. Convective heat transfer may also be classified as heat transfer in duct flow or in external flow (over cylinders, spheres, air foils or similar subjects). In the second case, the heat transfer process is essentially concentrated in a thin fluid layer surrounding the object (boundary layer).

Of special interest in such heat transfer processes is the knowledge of the heat flux from the surface of a solid object exposed to the flow. This heat flux q_w per unit area and time is conventionally described by Newton's equation

$$q_w = h(T_w - T_f) \quad (3)$$

where T_w is the surface temperature and T_f is a characteristic temperature in the fluid. This equation defining the heat transfer coefficient h is convenient because in many situations the heat flux is at least approximately proportional to the temperature difference $T_w - T_f$. Information on the heat transfer coefficients can be obtained by a solution of the Navier-Stokes equations describing the flow of a viscous fluid and the related energy equation, or they are found by experimentation. The availability of electronic computers has tremendously increased our ability to study heat transfer analytically at least for laminar flow, whereas in turbulent flow the bulk of our information is based on experiments. Such experimentation is made difficult by the large number of parameters involved. Dimensional analysis has therefore been applied to reduce the number of influencing parameters, and relations for convective heat transfer are correspondingly presented in modern handbooks as relations between dimensionless parameters. Such an analysis demonstrates for instance, that heat transfer in forced flow can be described by a relation of the form

$$Nu = f(Re, Pr) \quad (4)$$

in which the Nusselt number Nu is a dimensionless parameter $\frac{hL}{k}$, containing the heat transfer

coefficient h ; the Reynolds number $Re = \frac{\rho V L}{\mu}$ describes essentially the nature of the flow; and the Prandtl number $Pr = \frac{c_p \mu}{k}$ can be considered as a dimensionless transport property characterizing the fluid involved. L and V are an arbitrarily selected characteristic length and velocity, respectively, ρ denotes the density, μ the viscosity, and c_p the specific heat of the fluid at constant pressure. Occasionally the Stanton number, $St = \frac{Nu}{Re Pr}$, is used instead of the Nusselt number

as a dimensionless expression of the heat transfer coefficient. Equation (4) is based on the assumption that the thermodynamic and transport properties involved in the heat transfer process can be considered as constant. Larger variations of such properties are usually accounted for by additional terms in Eq. (4) expressing the ratio of the varying transport properties or of parameters (temperature, pressure) on which they depend. Fluids occurring in nature cover a very large range of Prandtl numbers. Liquid metals, for instance, have values of order 0.001 to 0.01. Gases have values between 0.6 and 1, and oils have values up to 10 000 and more. Some heat transfer relations for forced convection are presented in Table 1. Relations for other situations can be found in the various texts mentioned at the end of this section or in corresponding handbooks. With regard to the relations in Table 1 and other similar equations, it has to be kept in mind that they are valid over a restricted range of the independent parameters only.

Heat transfer by free convection is described by relations of the form

$$Nu = f(Gr, Pr) \quad (5)$$

In this equation, the Grashof number

$$Gr = \frac{\rho^2 g \beta (T_w - T_f) L^3}{\mu^2}$$

(where g is the gravitational constant, β is the thermal expansion coefficient, T_f is the fluid temperature at a distance where it is not influenced by the heated or cooled object with surface temperature T_w) replaces the Reynolds number. Sometimes a dimensionless parameter called Rayleigh number ($Ra = Gr Pr$) is used instead of the Grashof number. Equation (5) assumes again that the fluid properties involved are nearly constant. Examples for such relations are also contained in Table 1. Examples for free convection situations are the heat transfer from a heating register in the room. Free convection is also an important factor in the establishment of the temperature in the atmosphere. In the free convection relations of Table 1 and in Eq. (5), it has been assumed that the convection flows are generated by the gravitational field. Natural convection can also be created by other body forces, like centrifugal and Coriolis forces or electromagnetic forces.

TABLE 1. RELATIONS FOR CONVECTIVE HEAT TRANSFER

*Forced Convection**Channel Flow*

Flow through a tube:

laminar ($Re < 3000$)

$$Nu = 3.65$$

turbulent ($Re > 3000, Pr > 0.6$)

$$Nu = 0.116 (Re^{2/3} - 125) Pr^{1/3}$$

$$\left(Nu = \frac{hD}{k}, Re = \frac{\rho D V}{\mu} \right)$$

 D - diameter, V - mean velocity
External Flow

Flat plate parallel to flow:

laminar ($1000 < Re < 500000, Pr > 0.6$)

$$Nu = 0.332 \sqrt{Re} \sqrt{Pr}$$

turbulent ($Re > 500000, Pr > 0.6$)

$$Nu = \frac{0.0297 Re^{4/5} Pr}{1 + 1.3 Re^{-1/4} Pr^{-1/4} (Pr - 1)}$$

$$\left(Nu = \frac{hx}{k}, Re = \frac{\rho V_\infty x}{\mu}, x = \text{distance from leading} \right)$$

 $\text{edge, } V_\infty = \text{velocity outside boundary layer}$
Cylinder normal to flow: $1 < Re < 4000$

$$Nu = 0.43 + 0.48 \sqrt{Re}$$

$$\left(Nu = \frac{hD}{k}, Re = \frac{\rho V_0 D}{\mu_1}, D = \text{diameter, } V_0 \right)$$

 upstream velocity
Natural Convection

Vertical flat plate:

laminar ($10^4 < Gr < 10^9$)

$$Nu = 0.508 Gr^{1/4} Pr^{1/2} (0.952 + Pr)^{-1/4}$$

turbulent ($Gr > 10^9$)

$$Nu = 0.0295 Gr^{2/5} Pr^{1/3} (1 + 0.494 Pr^{2/3})^{-1/5}$$

$$\left(Nu = \frac{hx}{k}, Gr = \frac{\rho^2 g \beta (T_w - T_f) x^3}{\mu^2}, x = \text{distance} \right)$$

 $\text{from leading edge, } T_w = \text{wall temperature, } T_f$
 $\text{fluid temperature at some distance from plate}$

(All surfaces are assumed to have uniform temperature)

Space does not permit the discussion of other heat transfer processes, although such processes have found increasing attention in recent years. Especially large heat transfer coefficients are created by a boiling or condensation process. Boiling heat transfer is therefore used in applications which have to deal with very large heat fluxes like chambers and nozzles of rockets or the anodes in electric arc devices. Heat transfer is also often combined with mass transfer processes. This is, for instance, the case in evaporation devices. Heat transfer may also occur combined with chemical reactions as in processes involving gases at very

high temperature where combustion, dissociation, or ionization occur.

Radiation. Energy can also be transferred from one location to another within a medium or from one medium to another in the form of photons (electromagnetic waves). Usually a multiplicity of wavelengths λ is involved in such energy transfer. In vacuum, all waves regardless of their wavelength move with the same speed $2.9977 \times 10^8 \text{ m/sec}$. In various substances, the wave velocity c changes somewhat with wavelength, and the ratio of the wave velocity in vacuum to the velocity in a substance is equal to the optical refraction index. Air and generally all gases have refraction indices which differ from one only in the fourth decimal. Their wave velocity is, therefore, practically equal to that in vacuum.

Prevost's principle states that the amount of energy emitted by a volume element within a radiating substance is completely independent of its surroundings. Whether the volume element increases or decreases its temperature by the process of radiation depends on whether it absorbs more foreign radiation than it emits or vice versa. One talks about thermal radiation when the emission of photons is thermally excited, i.e., when the substance within the volume element is nearly in thermodynamic equilibrium. The discussion in this section will be restricted to thermal radiation. For such radiation, Kirchhoff was able to derive a number of relations by consideration of a system of media in thermodynamic equilibrium. If j_ν indicates the co-efficient of emission, i.e., the radiative flux at the frequency ν emitted per unit volume into a unit solid angle, and α_ν is the co-efficient of absorption at the same frequency, that is, the fraction of the intensity of a radiant beam which is absorbed per unit path length, then one of these relations states

$$c^2 \frac{j_\nu}{\alpha_\nu} = f(T, \nu) \quad (6)$$

with c denoting the wave velocity. According to this relation, the combination of parameters on the left-hand side of the equation is a function of temperature T and frequency ν of the radiation only, but does not depend on the substance under consideration. Kirchhoff's law can also be expressed in parameters which refer to the interface of two media 1 and 2. It then takes the form

$$c^2 \frac{i_\nu}{\alpha_\nu} = f(T, \nu) \quad (7)$$

in which i_ν is the monochromatic intensity of the radiative flux at frequency ν originating in medium 2 and traveling through the interface into medium 1 per unit solid angle and area normal to the direction of the radiant beam. α_ν is the monochromatic absorptance or absorptivity, i.e. that fraction of a radiant beam approaching the interface in the medium 1 in the opposite direction that

* Frequency and wavelength are used interchangeably. They are connected by the relation $\lambda \nu = c$.

is absorbed in medium 2. c is the wave velocity in medium 1. Kirchhoff's law states that the combination of the parameters on the left-hand side of Eq. (7) is again a function of temperature and frequency only, but does not depend on the nature of the medium. A medium which absorbs all the radiation traveling into it through an interface ($\alpha_r = 1$) is called a blackbody. The intensity of radiation emitted by an arbitrary medium is, according to Eq. (7), in the following way related to the intensity of radiation i_{bb} emitted by a blackbody at the same temperature and frequency

$$\frac{i_\nu}{\alpha_r} = i_{bb} \quad (8)$$

From the consideration of a system in thermodynamic equilibrium, it is also easily shown that i_{bb} is independent of direction and that the total monochromatic radiant flux emitted by a blackbody per unit interface area and unit time is equal πi_{bb} .

The law describing the monochromatic intensity of radiation of a blackbody is given by Planck's equation

$$i = \frac{2h\nu^3}{c^2(e^{h\nu/kT} - 1)} \quad (9)$$

(where h is Planck's quantum constant and k is Boltzmann's constant). Figure 2 presents the wavelength dependence of the intensity of blackbody monochromatic radiation for a number of temperatures. It may be observed that for each temperature, the intensity has a maximum at a certain wavelength and that this maximum shifts toward short wavelengths with increasing temperature (Wien's law). The wavelength λ is plotted on the abscissa in microns μ ($1000\mu = 1$ mm). Our eye is sensitive to radiation in the range 0.4 to 0.7μ (the dashed range). It may be observed that for temperatures with which we

have largely to deal, the bulk of blackbody radiation is contained in the range of wavelengths larger than the visible ones (infrared range). This statement also holds for other media because Eq. (8) shows that no medium can have a monochromatic intensity which is higher than that of a blackbody. Only radiation coming from the sun has a major portion of the energy in the visible wavelength range (corresponding to a temperature of 6500°K).

The total energy flux q emitted per unit area and time from a blackbody can be obtained by integration of Eq. (9) over all frequencies and by multiplication of the result by π . For blackbody radiation into a vacuum (or with good approximation into a gas), the result is

$$q = \sigma T^4 \quad (10)$$

The Stefan-Boltzmann constant σ has the value $5.67 \times 10^{-8} \text{ W/m}^2 \text{ K}^{-4}$.

The following additional relation exists at an interface between two substances.

$$\rho_r + \alpha_r + \tau_r = 1 \quad (11)$$

This equation describes that the radiant energy in a beam approaching in a medium 1 the interface to a medium 2 is found again either as radiation reflected back into the medium 1 or absorbed in the medium 2 or transmitted through the medium 2 into other media or back into medium 1. The monochromatic reflectance or reflectivity ρ_r is the ratio of reflected to incident radiant energy, α_r is the corresponding ratio for the absorbed and τ_r for the transmitted energy. The vast majority of solids and liquids absorb radiant energy over most wavelengths in the infrared range within a very thin layer adjacent to the interface (of order 1μ to 1 mm). In heat transfer calculations, it can therefore usually be assumed that the transmissivity of such substances is equal to zero and that reflectivity and absorptivity are connected to the temperature of the interface. One talks then often in a simplified manner about radiative interchange between surfaces. Kirchhoff's law, Eq. (8), additionally connects the intensity of a beam emitted through the interface with the absorptivity and the intensity of a beam leaving a blackbody at the same temperature. Electromagnetic theory shows that electric nonconducting materials have generally high values of the absorptivity and correspondingly low values of the reflectivity. Metals (electric conductors), on the other hand, behave in the opposite way, having low absorptivity and high reflectivity values. This fact is utilized in aluminum-insulations and in vacuum thermos bottles. In the visible range, the appearance of surfaces of various materials to the eye already supplies information on approximate values of the reflectivity and absorptivity. A white surface, for instance, has a very low absorptivity. Gases behave differently with respect to radiation. They need fairly large layers in order to absorb the major part of incident radiation and radiate only in restricted wavelength ranges whereas solids and liquids have a more continuous spectrum.

FIG. 2.

Values for the radiation properties (ρ_r , α_r , τ_r) together with the relations for blackbody radiation are the basis of calculations to determine heat exchange by radiation in a system with locally varying temperature. Calculations of such interchange are in general very involved, especially when substances with small absorption coefficients are involved. The formulation of such interchange leads to integral differential equations. The reader has in this connection to be referred to the books listed at the end of this section, and only a few relations for simple geometries will be presented here. Consider two area elements, dA_1 and dA_2 , belonging to two blackbodies with the temperatures T_1 and T_2 . The distance between the two area elements is s , and β_1 and β_2 are the angles between the two surface normals and the interconnecting line. The following equation then describes the net heat transfer dQ from area element dA_1 to area element dA_2 per unit time assuming that no radiation is absorbed or emitted in the space between the two surfaces

$$dQ = \frac{\cos \beta_1 \cos \beta_2}{\pi s^2} dA_1 dA_2 \sigma (T_1^4 - T_2^4) \quad (12)$$

If non-black surfaces are involved, then the process of radiant interchange is much more involved, since part of the incident radiation is now reflected from the surfaces and travels in this way back and forth until it is finally absorbed. Simple relations exist in this case for the radiative interchange between the surfaces of two concentric spheres or cylinders with areas A_1 and A_2 and temperatures T_1 and T_2 . It is further assumed that both surfaces are emitting and reflecting in a perfectly diffuse way and that they are separated by a medium which does neither emit nor absorb radiation. The net monochromatic interchange $d\Phi_r$ between the two surfaces is then described by the equation

$$d\Phi_r = \frac{\pi}{\frac{1}{\alpha_{r1}} + \frac{A_1}{A_2} \left(\frac{1}{\alpha_{r2}} - 1 \right)} dA_1 (i_{br1} - i_{br2}) \quad (13)$$

The monochromatic intensities i_{br1} and i_{br2} are calculated with Eq. (9). The relation changes when the outer cylinder reflects radiation mirror-like (specularly) to

$$d\Phi_r = \frac{\pi}{\frac{1}{\alpha_{r1}} + \left(\frac{1}{\alpha_{r2}} - 1 \right)} dA_1 (i_{br1} - i_{br2}) \quad (14)$$

Both equations merge asymptotically into the same relation when the differences between the two radii become small. The corresponding relation then also holds for two parallel infinite planes. Equations (13) and (14) have to be integrated over all frequencies to obtain the net heat transfer between the two surfaces. The result is simple when the absorptances α_{r1} and α_{r2} are independent of frequency (gray surfaces). Equations (13) and (14) describe then the net heat

transfer, when i_{br1} and i_{br2} are replaced by $\frac{\sigma}{\pi} T_1^4$ and $\frac{\sigma}{\pi} T_2^4$, respectively.

HEISENBERG UNCERTAINTY PRINCIPLE

Classical physics is based on two assumptions that have been found experimentally to be untenable. The first of these is the existence of signals that can travel with infinite speed; the second is that the magnitude of the interaction between two systems can be reduced to arbitrarily small values. The realization that the speed of propagation of signals has a finite upper limit led to the development of relativity theory. The recognition of the existence of a finite quantum of action has been incorporated in quantum (wave) mechanics.

Quantum mechanics assigns a physical reality only to those variables whose value can, in principle, be experimentally determined. About the existence of phenomena or systems that cannot be experimentally observed, quantum mechanics is noncommittal. Questions regarding an isolated system are meaningless in quantum mechanics, for any observation made on such a system necessarily disturbs its isolation by at least one quantum of action. Heisenberg⁵ observed that any measurement made on a system destroys some of the knowledge gained about that system through previous measurements. Any prediction about the future course of a system must be contingent on a knowledge about the measurements that will be made on that system, and is subject to uncertainties introduced by the measurements. Whereas one might speculate with some reliability about the future course of a system under the restriction that no more measurements will be performed on it, such speculations would be physically meaningless, as they could not be experimentally confirmed or denied.

In the broadest sense, then, the Heisenberg Uncertainty Principle states that the partitioning of the universe into observer (either a human observer, or a recording device such as a photographic plate) and observed is subject to a finite inaccuracy; one might say that the "knife" or "pencil" that makes the partition has a finite "thickness", h .

The concept of a monochromatic beam of radiation is not a difficult one to accept. Yet the experimental determination of the frequency of such a beam requires an infinite time interval; any finite portion chopped from the beam is shown by Fourier analysis to have a spectrum of finite width, hence not a single frequency at all. Quantum mechanics does not deny the existence of a monochromatic beam, but it does render the assignment of a definite frequency in a given time interval meaningless.

Fourier analysis shows that the specifications of the time interval, Δt , and of the spectral width, $\Delta\nu$, are reciprocally related:

$$\Delta\nu \Delta t \geq 1 \quad (1)$$

This equation represents the uncertainty relation for classical waves: any attempt to specify the frequency at an instant of time results in a broadening of the frequency spectrum. This uncertainty relation applies to any wave, whether electromagnetic, acoustic, or otherwise.

Interference patterns observed when electron beams are reflected from crystalline surfaces³ or transmitted through thin metallic films⁷ indicate that these beams possess some wave characteristics. DeBroglie², by independent theoretical considerations (see WAVE MECHANICS), postulated the following relations between the dynamic variables, energy (E) and linear momentum (p) of the beam, on the one hand, and the wave variables, frequency (ν) and wavelength (λ), on the other:

$$E = h\nu \quad (2)$$

$$p = h/\lambda \quad (3)$$

Substitution of Eq. (2) in Eq. (1) gives the uncertainty relation between energy and time:

$$\Delta E \Delta t \geq h \quad (4)$$

For a beam of free electrons of mass m , traveling in the x direction, $\Delta t = m \Delta x/p_x$, where p_x is the linear momentum and Δx is the distance traveled in the time interval Δt . Since $E = p_x^2/2m$, $\Delta E \cong p_x \Delta p_x/m$, so that $\Delta E \Delta t = \Delta p_x \Delta x$, and

$$\Delta p_x \Delta x \geq h \quad (5)$$

The pairs of variables (E, t) and (p_x, x) are called canonically conjugate pairs of variables. In quantum mechanics, the operators corresponding to canonically conjugate variables do not commute (see QUANTUM THEORY). Heisenberg originally stated his uncertainty principle in the following form: the values of canonically conjugate variables of a given system can only be determined with a finite lower limit of accuracy.

Among the many important experimental phenomena illustrating the uncertainty principle is the COMPTON EFFECT. Here, a photon is scattered by an electron; the momentum of the photon is rendered uncertain as a result of its scattering by the electron, and the electron is moved from its original position by the impact received from

the photon. If we consider the photon and the electron as separate systems, then their interaction (the collision) introduces uncertainties for each system, given by Equation (5).

A general uncertainty relation follows from the postulates of WAVE MECHANICS. Consider two variables, a and b , of a system, whose operators are \mathcal{A} and \mathcal{B} . The expectation values of a and b are called \bar{a} and \bar{b} respectively. The uncertainties in a and b can then be defined quantitatively as their respective rms deviations from their expectation values; it follows from the postulates that

$$(\Delta a)^2 \equiv \oint \Psi^* (\mathcal{A} - \bar{a})^2 \Psi dq$$

where Ψ is the normalized wave function of the system under observation, and $\oint \dots dq$ indicates integration over all values of all coordinates. Similarly,

$$(\Delta b)^2 \equiv \oint \Psi^* (\mathcal{B} - \bar{b})^2 \Psi dq$$

If \mathcal{A} and \mathcal{B} are Hermitian,[†] $(\mathcal{A} - \bar{a})^2$ and $(\mathcal{B} - \bar{b})^2$ are also Hermitian. Therefore:

$$\begin{aligned} (\Delta a)^2 \cdot (\Delta b)^2 &= \oint \Psi^* (\mathcal{A} - \bar{a})^2 \Psi dq \cdot \oint \Psi^* (\mathcal{B} - \bar{b})^2 \Psi dq \\ &= \oint (\mathcal{A} - \bar{a}) \Psi (\mathcal{A} - \bar{a})^* \Psi^* dq \\ &\quad \cdot \oint (\mathcal{B} - \bar{b}) \Psi (\mathcal{B} - \bar{b})^* \Psi^* dq \\ &= \oint |(\mathcal{A} - \bar{a}) \Psi|^2 dq \cdot \oint |(\mathcal{B} - \bar{b}) \Psi|^2 dq. \end{aligned}$$

To put this product of two definite integrals in a more useful form, consider the function

$$f(q) = \lambda(\mathcal{A} - \bar{a}) \Psi + i(\mathcal{B} - \bar{b}) \Psi^*$$

where λ is real, and independent of coordinates, and $i \equiv \sqrt{-1}$. The function $|f(q)|^2$ must be non-negative:

$$\begin{aligned} \lambda^2 [(\mathcal{A} - \bar{a}) \Psi]^2 &- i\lambda [(\mathcal{A}^* - \bar{a}) \Psi^* (\mathcal{B} - \bar{b}) \Psi + \\ &+ (\mathcal{A} - \bar{a}) \Psi (\mathcal{B}^* - \bar{b}) \Psi^*] + |(\mathcal{B} - \bar{b}) \Psi|^2 \geq 0 \end{aligned}$$

When the left-hand side of this inequality is integrated over all values of all coordinates:

$$\begin{aligned} \lambda^2 (\Delta a)^2 + (\Delta b)^2 &+ i\lambda [\oint (\mathcal{A}^* - \bar{a}) \Psi^* (\mathcal{B} - \bar{b}) \Psi dq + \\ &- \oint (\mathcal{A} - \bar{a}) \Psi (\mathcal{B}^* - \bar{b}) \Psi^* dq] \geq 0 \end{aligned}$$

Since λ is real, the left-hand side of this inequality becomes negative unless the discriminant becomes zero or negative:

$$\begin{aligned} 4(\Delta a)^2 (\Delta b)^2 &\geq -[\oint (\mathcal{A}^* - \bar{a}) \Psi^* (\mathcal{B} - \bar{b}) \Psi dq + \\ &- \oint (\mathcal{A} - \bar{a}) \Psi (\mathcal{B}^* - \bar{b}) \Psi^* dq]^2 \end{aligned}$$

[†] An operator \mathcal{F} is Hermitian, if for any properly behaved functions u and v : $\oint u \mathcal{F} v dq = \oint v \mathcal{F}^* u dq$, where $*$ indicates complex conjugation. Quantum mechanical operators usually are, or can be made to be, Hermitian.

The right-hand side of this inequality is reduced as follows (remember that Ψ is normalized):

$$\begin{aligned} & \oint (\mathcal{A}^* - \bar{a}) \Psi^* (\mathcal{B} - b) \Psi dq - \oint (\mathcal{A} \Psi)^* \mathcal{B} \Psi dq + \\ & \quad - \bar{a} \oint \Psi^* \mathcal{B} \Psi dq - b \oint \Psi^* (\mathcal{A} \Psi)^* dq + \bar{a} b \\ & \oint (\mathcal{A} - \bar{a}) \Psi (\mathcal{B}^* - \bar{b}) \Psi^* dq - \oint (\mathcal{A} \Psi) (\mathcal{B} \Psi)^* dq + \\ & \quad - \bar{a} \oint \Psi (\mathcal{B} \Psi)^* dq - b \oint \Psi^* (\mathcal{A} \Psi) dq + \bar{a} b \\ \text{Since } b &= \oint \Psi^* \mathcal{B} \Psi dq = \oint \Psi^* (\mathcal{B} \Psi)^* dq, \text{ and} \\ \bar{a} &= \oint \Psi^* \mathcal{A} \Psi dq = \oint \Psi^* (\mathcal{A} \Psi)^* dq, \\ 4(\Delta a)^2 (\Delta b)^2 &\geq - [\oint (\mathcal{A} \Psi)^* (\mathcal{B} \Psi) dq + \\ & \quad - \oint (\mathcal{A} \Psi) (\mathcal{B} \Psi)^* dq]^2 \end{aligned}$$

Since \mathcal{A} and \mathcal{B} are Hermitian

$$\begin{aligned} \oint (\mathcal{A} \Psi)^* (\mathcal{B} \Psi) dq &\equiv \oint (\mathcal{B} \Psi) (\mathcal{A} \Psi)^* dq = \\ &= \oint \Psi^* \mathcal{A} \mathcal{B} \Psi dq, \\ \oint (\mathcal{A} \Psi) (\mathcal{B} \Psi)^* dq &= \oint \Psi^* \mathcal{B} \mathcal{A} \Psi dq \quad (6) \\ \therefore 4(\Delta a)^2 (\Delta b)^2 &\geq - [\oint \Psi^* (\mathcal{A} \mathcal{B} - \mathcal{B} \mathcal{A}) \Psi dq]^2 \\ \text{and } |\Delta a| |\Delta b| &\geq \frac{1}{2} \oint \Psi^* (\mathcal{A} \mathcal{B} - \mathcal{B} \mathcal{A}) \Psi dq \end{aligned}$$

According to the postulates of wave mechanics, the operators for momentum and position are given respectively by: $\mathcal{P} = -i\hbar \nabla$, where $\hbar = h/2\pi$, and $\mathcal{Q} = q$ (multiplication by q).

For linear motion in the x direction, $\mathcal{P}_x = -i\hbar \partial/\partial x$, $\mathcal{Q} = x$. Hence $(\mathcal{P}\mathcal{Q} - \mathcal{Q}\mathcal{P})\Psi = -i\hbar (c/\partial x)(x\Psi) = i\hbar x(\partial\Psi/\partial x) = i\hbar\Psi$. When this expression is substituted into Eq. (6), it follows that:

$$|\Delta p_x| |\Delta x| \geq \hbar/4\pi$$

which is in agreement with Eq. (5). Equation (4) can be similarly derived from the postulates of wave mechanics by setting $\mathcal{E} = (i\hbar/2\pi)(\partial/\partial t)$, $\mathcal{T} = t$.

HIGH-VOLTAGE RESEARCH

High-voltage research deals with phenomena evoked by high voltages and intense electric fields, with the behavior of dielectrics and electrical components under such electrical stress, and with the utilization of electrostatic fields and forces for various purposes of science and industry. In the laboratory, this electrical stress is produced by the presence of electric charge on the opposing surfaces of two electrodes between which a voltage is applied. Pulsed, alternating and constant voltages ranging from a few kilovolts to 10 MV have been used in such studies. In nature, air currents and water precipitation cause electric charge to become separated between cloud and earth or between clouds; the stressed region may reach electrical pressure differences in excess of 1000 MV. Lightning, a rapid high-current discharge, completes the breakdown of the over-stressed air and dissipates the accumulated electrical energy. Many aspects of this natural high-voltage phenomena have been the subject of investigation because of their scientific interest and the danger of lightning to life and to susceptible structures such as electric power systems.

In the industrial high-voltage laboratory, the direct and induced effects of lightning discharges on electrical apparatus are often simulated by high-voltage impulse generators. These use the Marx method of first slowly charging a number of condensers in parallel and then suddenly connecting them in series by spark-gap switches which at the same instant impress the multiplied voltage upon the test circuit. A typical voltage wave produced by such impulse generators rises to its peak value of several million volts in $1 \mu\text{sec}$ and then diminishes exponentially reaching half-voltage in $10 \mu\text{sec}$.

Electric Field between High-voltage Electrodes. The region between and around electrodes which have been charged by the application of a voltage V between them is occupied by the electric field of that charge. In an isolated system, the positive electrode has a deficiency of electrons exactly equal to the excess electrons on the negative electrode. The amount of electric charge Q on either electrode surface at any instant is given by $Q = CV$ where Q is in coulombs and C is the capacitance of the electrode system in farads. Energy is stored in the electrically stressed space between the electrodes; the amount of this electrical energy W can be expressed in terms of applied voltage or separated charge by $W = CV^2/2 = Q^2/2C$ joules.

The electric field intensity at any point is defined by the magnitude and direction of the force which would be experienced by a unit positive charge placed in the field at that point. Following Faraday, if we define a line of electric flux as a line drawn so that its direction is everywhere the direction of the force on a positive particle, and require that one line must originate on each unit positive charge and terminate on each unit negative charge, then the lines of flux

will map out the electric field and the lines per unit area will be directly related to the electrical field intensity E . The electrostatic force acting on a particle with charge q placed in an electric field of intensity E volts per meter is given by $f = qE$ newtons. The electric field distribution depends upon the geometry of the electrodes but is affected by the presence of dielectric materials or of charged particles; a quantitative picture of the static or changing field picture is usually essential to high-voltage research.

Objectives of High-voltage Research. From antiquity to the present, the history of high-voltage research sparkles with many names well-known in electrical science—Thales of Miletus, von Guericke, Newton, Franklin whose kite experiment established the identity of natural lightning and electricity, Cavendish, Faraday, and Roentgen whose discovery of x-rays in 1895 marked the beginning of the atomic age. During the 60 years centered on the turn of the twentieth century, physicists studied the passage of electricity through gases at normal and reduced pressure, sought an understanding of long sparks and corona in atmospheric air, measured the conductivity and breakdown strength of liquid dielectrics, and examined the flashover of solid insulators in these media. More recent research has been concerned with the electrical strength and dielectric losses of many solid dielectrics from porcelain to hydrocarbon polymers, the increasing voltage-insulating ability of gases with pressures extending to scores of atmospheres, and the mechanisms which lead to electrical conduction and breakdown between electrodes immersed in high vacuum.

Research in the high-voltage field may also be directed at testing and increasing the insulation strength of power equipment subject to lightning or switching surges. The increasing trend toward higher voltages for the transmission of electric power over long distances has directed research toward reduction of radio interference and power loss by corona and surface leakage from high-voltage transmission line conductors and their suspension insulators. The need to bring such power into urban areas has produced the requirement for ac power cables in which the center conductor is reliably insulated for hundreds of kilovolts above earth. The inherent efficiency and stability of dc power transmission have led to the development of more adequate high-voltage rectification and conversion apparatus. For these purposes, the low-pressure metallic vapor tube has reached the highest power levels though solid state devices offer much promise for high-voltage, high-power switching.

In the field of science and medicine, high-voltage research seeks improved methods of producing high constant voltages, of measuring and stabilizing such voltages, and of applying them to the acceleration of atomic ions and electrons to high energies. Such particle accelerators are needed for nuclear structure research; for the study of the properties of energetic atoms, electrons, x-rays, and neutrons; for the treatment

of deep-seated tumors with energetic particles and radiation, and for the radiation processing of materials.

Industrial objectives of high-voltage research include the development of high-power, high-frequency tubes and their power supplies for radar and long-range radio communication, the ionization of particulate matter by corona and its electrostatic collection as in smoke and chemical precipitators, and the elimination of electrostatic hazards which arise in processes such as the transfer or mixing of volatile hydrocarbons, dusts, and explosive gases.

HISTORY OF PHYSICS

Sir J. J. Thomson, discoverer of the electron, in his address on the nature of light, at Cambridge, England in June 1925, summarized very well the most important years in the growth and evolution of physical science. He stated that "thirty years ago I would have little to say about the nature of light whereas today it is the story of the entire physics." Thomson evidently referred to that dramatic period when the triumphant rise of nineteenth century physics reached its climax in the last decade of that century, with several revolutionary discoveries that symptomatized a new era. The nineteenth century represents such an overwhelming milestone in the unfolding process of man's knowledge of the physical world and its laws that in a brief account it is bound to dwarf all other periods into relatively fleeting time intervals. As a mighty mountain top, nineteenth century physics alone offers an eloquent panorama of the place and role of scientific discipline in the history of civilization.

Physics, as we know it today, is a relatively young science. As an independent field, it had its actual beginning with the age of Renaissance. Then distinctly associated with the pioneering work of Galileo, it was firmly established by Newton and his mathematization of the processes of physical ideas. Fragmentary rudiments of physics can, of course, be traced to the famous fountainheads of western civilization in the ancient river civilizations of Egypt and Mesopotamia and above all to their clearing house, ancient Greece. Whatever physics there was, it had its sustenance in a close association with astronomy, or astrology as it

was then known, man's truly oldest science. Its adepts at that time were philosophers rather than scientists. Having some portentous fear of and aversion toward experiment, they were timid observers of the majestic natural phenomena. Out of the ages of mythological mentality, Socratic ratiocination emerged in the ancient Greek miracle, and in the complex maze of natural phenomena tried to "save the appearances." This was achieved through philosophical speculation. Aristotle, a giant in pure philosophy, also wrote considerably on physics, yet his erroneous ideas on mechanics, due to his undisputed authority for many centuries, played a negative if not paralyzing role in the field of physical science. Some less-known thinkers such as Democritus remained in the background, although with their sound ideas on the nature of matter and space they could have had a strongly catalytic influence on the subsequent growth of physics.

The physical science of antiquity can be summed up in a most appropriate way by reference to the ancient Alexandrian school or library. This library, as a form of academy, symbolizes amazing accomplishments where almost all major fields of science were more or less apprehended in their rudiments or fundamentals. This center, shining like its lighthouse, Pharos—one of the seven wonders of the world—represents the integration of all knowledge on the nature of world "physis" as gathered since the famous Pythagorean school up to the climax attained in this Greek colonial city in Egypt. It includes a galaxy of names which left permanent traces in the formative state of physical science. Euclides' *Stoicheia* and Ptolemy's *Almagest* are probably its most precious heritage.

The age of antiquity where the appearance of natural science is associated with the first rise of rational thought in the world of mythology came to an end with the decline of the Alexandrian school. This occurred within two centuries, following the destruction of the library first by the Christians in 390 A.D. and in 642 A.D. by the Mohammedans. A millenium of the medieval era followed, described usually as the "dark ages." Physics, which demands objectivity, had little chance in face of all the pervading and forceful sacerdotal propaganda. Nevertheless, the historian's truth even there was evident: When it grows dark enough, stars come out. After its initial iconoclastic zeal, Islam reversed its attitude toward ancient learning and some of its scholars carried very high the torch of impartial studies while the Christian western world's concern was the salvation of the soul. Thus, the works of the ancient Greek philosophers, that encouraged interest in physical science, first reached Europe in translation from Arabic texts. Two church fathers, however, prove that all was not darkness in this age. St. Augustine, Bishop of Hippo, and St. Thomas Aquinas with their penetrating ideas stood at the fringes of such physics that responded to the dream of medieval man.

The all-powerful ecclesiastic rulers could not escape their decadence, and a change of tide was

inevitable. Whether it was the ecumenical meeting in Florence, in 1438, with Byzantine and Roman delegates gathered from both factions of the divided Christian world, or whether it was the life and work of that most unusual genius, Leonardo da Vinci, 1452-1519, the new stream of Renaissance relentlessly heralded an unprecedented era. Above all, it was the science of physics which, with the pioneers of astronomy, was to start its expansion destined to change the face of the world. Leonardo da Vinci in Italy and Nicholas Copernicus in Polish Pomerania (1473-1543) are probably most responsible for the wave of the future in which physics obtained an impulse as never before in history. As contemporaries, both were born still deep within the medieval society in widely different parts of Europe, yet their work corresponded and their accomplishments are firmly established in the foundations of classical physics.

The actual beginning of physics, however, is undoubtedly associated with Galileo Galilei (1564-1642). Standing at the cradle of physics, Galileo confronted a herculean task befitting his versatile genius. His mind displayed an inexhaustible industry and imagination when he took up the defense of the Copernican heliocentric system into the realm of the physical laboratory. Very few of his opponents were aware that through his ingenious demonstrations, such as rolling balls along an inclined plane, he would build lasting foundations of modern mechanics. It is rather curious that a man, most popular for his telescope which he did not invent, has gained undying glory for the introduction of modern scientific method, based upon experimentation. Galilean science is synonymous with empiricism and aposterioristic truth, i.e., that which is acquired by experience. Thus, Galileo as a pioneer of a new science experienced the full impact of opposition by his contemporaries, the ruling Scholastic doctrinaires, who advocated the dogma of aprioristic truth represented by Aristotelian speculative philosophy. It was at this stage that Aristotle's exponents misused his philosophy to the detriment of the healthy advancement of physics. The planetary currents heralding the new age, however, were invincible.

While Galileo died under house arrest and in disgrace, and that enthusiastic defender of Copernicanism, J. Kepler, died in misery, all glory and recognition were heaped upon Isaac Newton during his lifetime. It is significant that he was born the year Galileo passed away, 1642. The notable inscription on Newton's tombstone in Westminster Abbey characterizes the gratitude of his nation "Mortals should congratulate themselves that such a spiritual knight was born amongst them." Yet Newton was modest enough to give credit to the giants on "whose shoulders he was sitting," as he once described his own work. *Principia*, his opus major, stands out among the few greatest products of the human intellect. We use the term Galilean science, but classical physics is referred to as Newtonian physics, associated with the world view of the Newtonian

universe. This was considered the final state of perfection of physics whose advancement, as Albert Michelson commented, would consist only in the position of the decimal point.

Newtonian physics, formulated in three laws of motion and climaxed by the universal law of gravitation, continued in its progressive refinement in order to reach its triumphant culmination in the nineteenth century. Its primary hallmark is the mathematization of space. Mathematical physics was described by Imanuel Kant as the greatest achievement of the human intellect. Indeed, it had a most fascinating confirmation in the mathematical discovery of the planet Neptune by J. C. Adams and Leverrier, in 1845. Laplace produced an overwhelming impression on the entire century when, in 1798, he used the rigor of mathematics to formulate his genial hypothesis on the origin of the solar system. The traditional heritage of the association of astronomy with physics is alive with Galileo and Newton, for both were astronomers and physicists. From that time on, the gap widened until now we have physicists who are almost complete strangers to astronomy.

With the culminating period of fruition, Newtonian physics is signalized by legions of great names as builders of our view of the physical world. It is possible here to note only a few principal milestones, each a giant of his own in a panoramic view of the glorious century. From Laplace at the beginning of the nineteenth century, the epic unfolds from Avogadro to Faraday, from Carnot to Helmholtz and Kelvin, attaining its peak in Maxwellian equations formulating the electromagnetic theory of light. These equations were impressively described by the physicist, Boltzmann, when he quoted Goethe's Faust: "Who was the god who wrote these lines?" Yet, these mathematical equations that so well described the natural processes, pointed inevitably to a deterministic universe. It was also a mechanistic universe. Thus, the nineteenth century physicist sought to create a model of such a universe. The corpuscular-kinetic nature of the universe, as seen by the physicist of the Victorian age, appeared only as a huge machine. It was a universe that offered no mysteries that could not be resolved in due course of time. Ultimately the universe was knowable and predictable. This *weltanschauung* (world view) of triumphant physics encouraged the rise of materialistic philosophy that was actually shaped by Marx and Engels into dialectical materialism, destined to become the official doctrine of the ruling communist state of the twentieth century.

Newtonian physics was not destined to remain the last form of knowledge. The turn of the twentieth century once again witnessed another tidal wave that changed the course of the evolution of physics. Whereas society at present lives by the impact of physics produced by its rise in the previous century, the revolutionary discoveries

that occurred in physics around 1895-1905 contain unfathomable, portentous consequences for the future. Becquerel's radioactivity, Roentgen's x-rays, Thomson's electron, Planck's quantum, Einstein's relativity, represent a revolution that will carry man incomparably farther into the mysteries of the universe than the Copernican revolution ever did. Heisenberg's principle of indeterminacy in the realm of microphysics not only discards the once cherished Laplacean determinism but points to the existence of a universe incomparably more complex than indicated by Newtonian mechanism. "It is not the discovery of an outlying island," stated Sir J. J. Thomson, then President of the Royal Society at the announcement of the first empirical confirmation of Einsteinian relativity in 1919, "it is a whole continent of new scientific ideas. It is the greatest discovery in connection with gravitation since Newton enunciated his principle."

Yet, it was still a quarter of a century before an even greater dramatic confirmation of the Einsteinian formula of the equality of energy with the product of mass and the square of the velocity of light, which marked, with a great human tragedy, the beginning of the age of nuclear energy. It is this aspect of modern, nuclear physics which through the atomic microcosmos reunites the physicist with the astrophysicist. The latter, in turn, investigates stellar laboratories in the macrocosmos where matter is subjected to conditions inaccessible to any terrestrial laboratories. This teamwork, in addition to the supreme geometrization of space-time of relativistic physics is bound to unveil new wonders of the heretofore unimaginable Einsteinian universe. Yet Einstein once humbly retorted to a eulogy on his great discoveries: "All I did was to study the history of physics."

HYDRODYNAMICS, See FLUID DYNAMICS.

I

IMPULSE AND MOMENTUM

The concept of impulse and momentum derives directly from Newton's law of motion.

Consider first the case of *linear* impulse and *linear* momentum. Newton's law states that in the proper frame of reference, force is equal to the (time) rate of change of momentum, where momentum is defined as the product of mass and velocity. Consider a force F acting for a time Δt on a particle of mass m , thereby changing its velocity from v_1 to v_2 . The rate of change of momentum in this case is the change of momentum divided by the time interval during which the change occurs. Thus, Newton's law states

$$F = \frac{(mv)_2 - (mv)_1}{\Delta t}$$

Now if we multiply each side of this equation by Δt , we obtain

$$F \Delta t = (mv)_2 - (mv)_1$$

The left-hand side of this equation, $F \Delta t$, representing the product of a force and the time interval through which the force acts, is called "impulse." Thus, this equation states what is often known as the *Law of Impulse and Momentum*: Impulse is equal to the change of momentum.

It becomes apparent that a body will experience the same change of momentum irrespective of the separate values of F and Δt as long as their product $F \Delta t$ is the same. Thus, a large force acting briefly may have the same net effect as a smaller force acting longer, if the two impulses are the same. Going to the limit, we may consider an infinite force acting for an infinitesimal time such that their product remains a finite quantity. Under the action of such an impulse, a body will experience an instantaneous change of velocity. A common example is the change of velocity of a baseball as it is hit by a bat. For all practical purposes the change occurs instantaneously.

As a consequence of the Law of Impulse and Momentum described above, we find that if the total force is zero, so is the total impulse, and the momentum will remain unchanged. This is known as the *Conservation Law of Momentum*. It applies either to one particle or to a system of particles. Consider, for instance, the collision of two billiard balls, A and B. Taking each ball separately, the impulse on A by B is equal in magnitude but opposite in direction to the impulse on B by A. Thus, upon collision, the change of momentum of

A is also equal and opposite to that of B. On the other hand, if we take *both* A and B as our system, then the two impulses are acting on the same system. Since the two are equal and opposite, they cancel out and the total impulse on this system is zero. The Conservation Law of Momentum then predicts that the total momentum of the system (which is the sum of momenta of all particles in the system) remains a constant no matter what goes on in the system.

The Conservation Law of Momentum forms one of the basic cornerstones in physics and engineering. Its application is all-pervading, from the motion of stars to the encounter and scattering of molecules, atoms and electrons.

We will now continue our discussion at a more precise level. First of all, in calculating the momentum mv , the mass m should be the relativistic mass defined as

$$m = \frac{m_0}{\sqrt{1 - (v/c)^2}}$$

where m_0 is the rest mass, i.e., mass at zero velocity, and c is the velocity of light. It is seen that at velocities much less than the velocity of light, the relativistic mass and the rest mass are indistinguishable. Secondly, both force and velocity are vector quantities, i.e., they have a magnitude and a direction and obey the parallelogram law of addition, and we shall use letters \mathbf{F} and \mathbf{v} to represent them. Finally, as the time interval Δt approaches zero as a limit, the rate of change of momentum during Δt becomes a derivative and Newton's law becomes:

$$\mathbf{F} = \frac{d}{dt}(m\mathbf{v})$$

After integrating each side of this equation with respect to time t and taking the integration limits from $t = t_1$ to $t = t_2$, the result is:

$$\int_{t_1}^{t_2} \mathbf{F} dt = (m\mathbf{v})_2 - (m\mathbf{v})_1$$

The integral on the left-hand side is called "impulse," and we again reach the Law of Impulse and Momentum given previously. In evaluating this integral, we must know the variation \mathbf{F} as a function of time, i.e., $\mathbf{F} = \mathbf{F}(t)$. Furthermore, in applying this law to a system of particles, we need only to count those impulses that are caused by *external* forces acting on the

particles due to sources outside the system. As has been illustrated by the previous example on two billiard balls, the *internal* forces that any two particles exert on each other will generally cancel out if both particles are included in the system.

Up to this point we have discussed the laws of linear impulse and linear momentum. Entirely similar laws hold for *angular* impulse and *angular* momentum. The angular momentum of a particle about a point O is defined as

$$\mathbf{L} = \mathbf{r} \times m\mathbf{v}$$

where \mathbf{r} is the radius vector from O to the particle. The moment of force or *torque* about O is defined as

$$\mathbf{T} = \mathbf{r} \times \mathbf{F}$$

If we take the cross product of \mathbf{r} with each side of the expression for Newton's law as given before, we obtain

$$\mathbf{r} \times \mathbf{F} = \mathbf{T} = \mathbf{r} \times \frac{d}{dt}(m\mathbf{v})$$

The right-hand side can be identified to be just $d\mathbf{L}/dt$ on account of the vector identity:

$$\frac{d\mathbf{L}}{dt} = \frac{d}{dt}(\mathbf{r} \times m\mathbf{v}) = \mathbf{v} \times m\mathbf{v} + \mathbf{r} \times \frac{d}{dt}(m\mathbf{v})$$

where the first term on the right-hand side vanishes. Thus,

$$\mathbf{T} = \frac{d\mathbf{L}}{dt}$$

We now integrate this equation with respect to t and take the integration limits from $t = t_1$ to $t = t_2$. The result is

$$\int_{t_1}^{t_2} \mathbf{T} dt = \mathbf{L}_2 - \mathbf{L}_1$$

Analogous to the linear impulse, we may call the integral on the left-hand side of the above equation the angular impulse. Thus this equation states: Angular impulse is equal to the change of angular momentum. In particular, if the total torque is zero, so is the total angular impulse, and the angular momentum will remain unchanged. This is known as the *Conservation Law of Angular Momentum*.

INDUCED ELECTROMOTIVE FORCE

Electromotive force and voltage drop are usually regarded as synonymous. When an electromotive force, or simply emf, is impressed on a closed metallic circuit, current results. The emf along a specified path C in space is defined as the work per unit charge W/q done by the electromagnetic fields on a small test charge moved along C . Since work is the line integral of force \mathbf{F} , the work per unit charge is the line integral of the force per unit charge. Letting \mathbf{F}/q denote the vector electromagnetic force per unit charge in newtons per coulomb, we have

$$\text{emf} = \int_C \frac{\mathbf{F}}{q} \cdot d\mathbf{l} \text{ volts} \quad (1)$$

The scalar product $(\mathbf{F}/q) \cdot d\mathbf{l}$ is the product $(F/q) \cos \theta dl$, with θ denoting the angle between the vectors \mathbf{F}/q and $d\mathbf{l}$.

The electric force per unit charge is the electric field intensity \mathbf{E} (volts per meter) and the magnetic force per unit charge is $\mathbf{v} \times \mathbf{B}$, with \mathbf{v} denoting the velocity of the test charge in meters per second and \mathbf{B} denoting the magnetic flux density in webers per square meter. In terms of the smaller angle θ between \mathbf{v} and \mathbf{B} , the cross product $\mathbf{v} \times \mathbf{B}$ is a vector having magnitude $vB \sin \theta$; the direction of the vector $\mathbf{v} \times \mathbf{B}$ is normal to the plane of the vectors \mathbf{v} and \mathbf{B} , with the sense of that of the extended thumb of the right hand oriented so that its fingers curl through the angle θ from \mathbf{v} toward \mathbf{B} . As the total force per unit charge is $\mathbf{E} + \mathbf{v} \times \mathbf{B}$, the emf in terms of the fields is

$$\text{emf} = \int_C (\mathbf{E} + \mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \quad (2)$$

It might appear from Eq. (2) that the emf depends on the forward velocity with which the test charge is moved along the path C . However, this is not the case. If \mathbf{v} and $d\mathbf{l}$ in Eq. (2) have the same direction, then the vectors $(\mathbf{v} \times \mathbf{B})$ and $d\mathbf{l}$ are normal, and their scalar product is zero. Consequently, only the component of \mathbf{v} normal to $d\mathbf{l}$ can contribute to the emf. This component has value only if the differential path length $d\mathbf{l}$ has sideways motion. Thus \mathbf{v} in Eq. (2) represents the *sideways motion, if any, of $d\mathbf{l}$* . The fields \mathbf{E} and \mathbf{B} of Eq. (2) may be functions of time as well as functions of the space coordinates. In addition, the velocity \mathbf{v} of each differential path length $d\mathbf{l}$ may vary with time. However, Eq. (2) correctly expresses the emf, or voltage drop, along the path C as a function of time. That component of the emf consisting of the line integral of $\mathbf{v} \times \mathbf{B}$ is known as the *motional emf*, because it has value only when the path C is moving through a magnetic field, cutting lines of magnetic flux. For stationary paths there is no motional emf, and the voltage drop is simply the line integral of the electric field \mathbf{E} .

For an emf to exist along a stationary path, it is necessary to have an electric field present. As electric charges are surrounded by electric fields emfs are generated by devices that separate

charge. A familiar example is the battery, which utilizes chemical forces to separate charge. Some other methods of separating charge are the heating of a thermocouple, the exposure of a photocell to incident light, and the rubbing together of different materials. Electric fields are also produced by time-changing magnetic fields, and this principle is extensively exploited, as is motional emf, to generate electric power. The remainder of this article is devoted to electromotive force induced by magnetic means.

A fundamental law of electromagnetism, often called the *Maxwell-Faraday law*, or the *first law of electromagnetic induction*, states that the line integral of the electric field intensity \mathbf{E} around any closed path C equals $-\partial\phi/\partial t$, with ϕ representing the magnetic flux over any surface S having the closed path C as its contour. The positive side of the surface S and the direction of the line integral around the contour C are related by the right-hand rule; by this rule, the curled fingers are oriented so as to point around the loop in the direction of the integration and the extended thumb points out of the positive side of the surface S . The magnetic flux ϕ is the surface integral of the magnetic flux density \mathbf{B} ; that is,

$$\phi = \iint_S \mathbf{B} \cdot d\mathbf{S} \text{ webers} \quad (3)$$

In Eq. (3) the vector differential surface $d\mathbf{S}$ has area dS and is directed normal to the plane of $d\mathbf{S}$ out of the positive side. The partial time derivative of ϕ is defined as

$$\frac{\partial\phi}{\partial t} = \iint_S \frac{\partial\mathbf{B}}{\partial t} \cdot d\mathbf{S} \text{ volts} \quad (4)$$

and this is often referred to as the *magnetic current* through the surface S . For a moving surface S the limits of the surface integral of Eq. (4) are functions of time, but Eq. (4) still applies. It is important to understand that in evaluating $\partial\phi/\partial t$ over a surface that is moving in a region containing a magnetic field, we treat the surface at the instant under consideration as though it is stationary. The partial time derivative of ϕ is the time rate of increase of the flux over the surface S due only to the changing magnetic field \mathbf{B} ; any increase in ϕ due to the motion of the surface in the \mathbf{B} -field is *not* included. The Maxwell-Faraday law is

$$\oint_C \mathbf{E} \cdot d\mathbf{l} = -\frac{\partial\phi}{\partial t} \quad (5)$$

with ϕ being the magnetic flux in webers out of the positive side of any surface having the path C as its contour. The small circle on the integral sign indicates a closed path. We note from Eq. (5) that an electric field must be present in any region containing a time-changing magnetic field.

The application of Eq. (2) to a closed path C gives

$$\text{emf} = \oint_C \mathbf{E} \cdot d\mathbf{l} + \oint_C (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \quad (6)$$

Utilizing Eq. (5) enables us to write Eq. (6) in the form

$$\text{emf} = -\frac{\partial\phi}{\partial t} + \oint_C (\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l} \quad (7)$$

Thus the emf around a closed path consists, in general, of two components. The component $-\partial\phi/\partial t$ is often referred to as the *variational emf* (or *transformer emf*), and the second component is, of course, the motional emf.

In Eq. (7) the relation $(\mathbf{v} \times \mathbf{B}) \cdot d\mathbf{l}$ can, by means of a common vector identity, be replaced with $\mathbf{B} \cdot (\mathbf{v} \times d\mathbf{l})$. As \mathbf{v} is the sideways velocity of $d\mathbf{l}$, the vector $\mathbf{v} \times d\mathbf{l}$ has magnitude $v dl$ and direction normal to the differential surface dS swept out by the moving length $d\mathbf{l}$ in the time dt . Letting B_n denote the component of \mathbf{B} normal to this area, we note that $\mathbf{B} \cdot (\mathbf{v} \times d\mathbf{l})$ becomes $B_n v dl$, and Eq. (7) can be written

$$\text{emf} = -\left[\frac{\partial\phi}{\partial t} + \oint_C B_n v dl \right] \quad (8)$$

Clearly the integral of $B_n v$ around the closed contour C , with t denoting the magnitude of the sideways velocity of each $d\mathbf{l}$, is simply the time rate of increase of the magnetic flux over the surface bounded by C due to the path C cutting lines of magnetic flux. Hence, the complete expression in brackets is the time rate of increase of the magnetic flux ϕ , over any surface S bounded by the closed path C , due to the changing magnetic field and also due to the moving path cutting through the magnetic field. Equation (8) is often written

$$\text{emf} = -\frac{d\phi}{dt} \quad (9)$$

It is important to note carefully the distinction between Eqs. (5) and (9). Equation (5) is only the variational emf, and Eq. (9) is the sum of the variational and motional emfs. In Eq. (5), the partial time derivative of the magnetic flux ϕ is the rate of change of the flux due only to the time-changing magnetic field; in Eq. (9), the total time derivative is the rate of change of the flux due to the time-changing \mathbf{B} -field and also to the path cutting through the magnetic field. Of course, if the closed path is not cutting lines of magnetic flux, then Eqs. (5) and (9) are equivalent. It is also important to note that $d\phi/dt$ in Eq. (9) does not necessarily mean the total time rate of change of the flux ϕ over the surface S . For example, the flux over a surface S bounded by the closed contour C of the left-hand electric circuit of Fig. 1 is changing when the coil is being unwound by the rotation of the cylinder. However, as \mathbf{B} is static there is no variational emf, and since the conductors are not cutting flux lines, there is no motional emf. Consequently, $d\phi/dt$ as used in Eq. (9) is zero even though the flux is changing with time. Note that $d\phi/dt$ in Eq. (9) was defined as representing the bracketed expression of Eq. (8), and $d\phi/dt$ must not be more broadly interpreted.

FIG. 1. The current generator produces a steady magnetic flux in the iron cylinder, which rotates as the wire is pulled at A .

In the applications of the equations which have been presented, we must refer all flux densities and movements to a single specified coordinate system. In particular, the velocities are with respect to this system and are not relative velocities between conductors and moving lines of flux. Of course the coordinate system is arbitrarily selected, and *the relative magnitudes of the variational and motional emfs depend upon the selection*. Let us consider two examples.

Example 1. An electric generator is shown in Fig. 2. The parallel stationary conductors separated a distance l have a stationary voltmeter connected between them. The electric circuit is completed through a moving conductor that is connected electrically by means of sliding taps. This conductor is at $y = 0$ at time $t = 0$ and moves to the right with constant velocity $v = v\mathbf{a}_y$. The applied flux density \mathbf{B} , represented in Fig. 2 by dots, is $B_0 \cos \beta y \cos \omega t \mathbf{a}_z$. Unit vectors in the directions of the respective coordinate axes are \mathbf{a}_x , \mathbf{a}_y , and \mathbf{a}_z . Find the instantaneous voltage across the voltmeter.

Solution. Let S denote the plane rectangular surface bounded by the closed electric circuit, with the positive side selected as the side facing the reader. The counterclockwise emf around the electric circuit is $-\frac{d\phi}{dt}$, with ϕ signifying the magnetic flux out of the positive side of S . As $dS = l dy \mathbf{a}_x$, the scalar

product $\mathbf{B} \cdot d\mathbf{S}$ is $B_0 l \cos \beta y \cos \omega t dy$; integrating from $y = 0$ to $y = y_1$ gives

$$\phi = (B_0 l / \beta) \sin \beta y_1 \cos \omega t \quad (10)$$

with y_1 denoting the instantaneous y -position of the moving wire. The counterclockwise emf is found by replacing y_1 with vt and evaluating $-\frac{d\phi}{dt}$. The result is

$$\text{emf} = \omega B_0 l / \beta \sin \beta vt \sin \omega t = B_0 l v \cos \beta vt \cos \omega t \quad (11)$$

The variational (transformer) component is $-\frac{d\phi}{dt}$, which is determined with the aid of Eq. (10) to be $\omega B_0 l / \beta \sin \beta y_1 \sin \omega t$, with $y_1 = vt$. This is the first component on the right side of Eq. (11). Note that y_1 was treated as constant when evaluating the partial time derivative of ϕ . The motional emf is the line integral of $\mathbf{v} \times \mathbf{B}$ along the path of the moving conductor. As $\mathbf{v} \times \mathbf{B}$ is $-B_0 v \cos \beta y_1 \cos \omega t \mathbf{a}_z$ and as $d\mathbf{l}$ is $dz \mathbf{a}_z$, we evaluate the integral of $-B_0 v \cos \beta y_1 \cos \omega t dz$ from $z = 0$ to $z = l$, obtaining a motional emf of $-B_0 l v \cos \beta y_1 \cos \omega t$. This component results from the cutting of lines of magnetic flux by the moving conductor.

If the voltmeter draws no current, there can be no electromagnetic force on the free electrons of the wires. Therefore, *the emf along the path of the metal conductors, including the moving conductor, is zero*. The total voltage of Eq. (11) appears across the voltmeter.

FIG. 2. Elementary electric generator.

Example 2. Suppose the conductor with sliding taps in Fig. 2 is stationary ($v = 0$) and located at $y = y_1$. Also suppose that the magnetic field \mathbf{B} is produced by a system of steady currents in conductors (not shown in Fig. 2) that are moving with constant velocity $\mathbf{v} = v\mathbf{a}_y$. At time $t = 0$ the magnetic field \mathbf{B} is $B_0 \sin \beta y \mathbf{a}_x$. Determine the voltage across the voltmeter.

Solution. There is no motional emf because the conductors of Fig. 2 are stationary with respect to our selected coordinate system. However, the magnetic field at points fixed with respect to the coordinate system is changing with time, and hence there is a variational emf.

As the \mathbf{B} -field at $t = 0$ is $B_0 \sin \beta y \mathbf{a}_x$ and moving with velocity $v\mathbf{a}_y$, the \mathbf{B} -field as a function of time is $B_0 \sin [\beta(y - vt)] \mathbf{a}_x$. This is verified by noting that an observer at y_0 at $t = 0$ moving in the y -direction with the velocity v of the moving current-carrying conductors, would have a y -coordinate of $y_0 + vt$; hence according to the expression for \mathbf{B} , he would observe a constant field. The magnetic current density is

$$\partial \mathbf{B} / \partial t = -\beta v B_0 \cos \beta(y - vt) \mathbf{a}_x$$

The negative of the integral of this over the rectangular surface bounded by the electric circuit, with the positive side selected as the side facing the reader and with y limits of zero and y_1 , gives the counter-clockwise emf. The result is

$$\text{emf} = B_0 v [\sin \beta(y_1 - vt) + \sin \beta vt]$$

This is the voltage across the meter.

INDUCTANCE

Inductance is a ratio of a magnetic flux Φ to an electric current i . The unit is the henry; 1 henry \equiv 1 weber/ampere. The *mutual inductance* M of two circuits is defined as the ratio of the magnetic flux, linking with one circuit, to the current in the other

$$M_{12} = \frac{\Phi_2}{i_1}, M_{21} = \frac{\Phi_1}{i_2}$$

The *self-inductance* L of a single circuit is defined

as the ratio of the flux linking the circuit to the current flowing in the circuit.

$$L = \frac{\Phi}{i}$$

In the absence of any magnetic material, M and L depend only on the geometry of the circuits concerned. The mutual inductance of two circuits 1 and 2 can be calculated from the Neumann equation*

$$M_{12} = M_{21} = \frac{\mu_0}{4\pi} \oint_1 \oint_2 \frac{\mathbf{dl}_1 \cdot \mathbf{dl}_2}{r}$$

where \mathbf{dl}_1 and \mathbf{dl}_2 are vector elements of length in circuits 1 and 2, respectively, and r is the distance between these two elements. Note that this expression is completely symmetrical with respect to the two circuits. The self-inductance is calculated from the same equation, where the elements \mathbf{dl}_1 and \mathbf{dl}_2 are now situated on the same circuit. The double integral is evaluated by first keeping the position of \mathbf{dl}_2 fixed and integrating \mathbf{dl}_1/r around the circuit. The process is then repeated for all other elements such as \mathbf{dl}_2 , and the results are summed.

The *external inductance* of a circuit is the part of its self-inductance which is due to flux lying outside the surface of the conductor while the *internal inductance* is the contribution from the magnetic flux within the conductor itself.

If the current, and therefore the magnetic flux associated with it, varies with time, an electromotive force (emf) will be induced in any circuit linked by the flux. This provides an alternative method of defining inductance in terms of the emf induced by a given rate of change of current.

$$\mathcal{E}_2 = -M \frac{di_1}{dt}$$

$$\mathcal{E}_1 = -M \frac{di_2}{dt}$$

$$\mathcal{E} = -L \frac{di}{dt}$$

The negative signs are used to imply that the direction of the emf is always such as to tend to oppose the change of current (Lenz's law). Note, however, that although the self-inductance must always be positive, the mutual inductance of two circuits may be either positive or negative. An inductance of 1 henry corresponds to an induced emf of 1 volt for a rate of change of current of 1 ampere/sec.

In order to maintain a current i , the induced emf $-L di/dt$ must be balanced by an equal and opposite applied voltage so that the total applied voltage is

$$v = Ri + L \frac{di}{dt}$$

* μ_0 is the permeability of free space; $\mu_0 = 4\pi \times 10^{-7}$ henrys/m.

and the power supplied to the circuit is

$$vi = Ri^2 + \frac{d}{dt} \left(\frac{1}{2} Li^2 \right)$$

where the resistance R is a measure of the power dissipated. This equation shows another way of interpreting inductance, namely as a measure of the amount of energy stored in the magnetic field when a given current flows. The stored energy is $\frac{1}{2} Li^2$ joules when L is measured in henrys and i in amperes.

Electric circuit theory is based on the use of sinusoidally varying currents and voltages. When the current varies sinusoidally with time, the rate of change of current has the same time-waveform except for a phase shift of $\pi/2$ radians. This leads to the idea of a complex impedance, of which the real part is associated with the power lost from the circuit and the imaginary part is a reactance given by the ratio of the magnitude of the induced emf to that of the current. Since the phase of the applied voltage leads that of the current, the magnetically induced reactance is taken as being positive. We thus have

$$i = I \sin \omega t$$

$$v = Ri + L \frac{di}{dt}$$

The circuit impedance is Z where

$$Z = \frac{v}{i} = R + j\omega L$$

The self-inductance of a circuit can be regarded as a parameter which determines the inductive reactance presented to a sinusoidally varying current of given amplitude and frequency. In the same way, the mutual inductance determines the mutual reactance between two circuits.

Owing to magnetic hysteresis, the voltage and current-time waveforms cannot both be sinusoidal if any magnetic material is present. Under these conditions, the reactance is defined as the ratio of the fundamental-frequency components of the voltage and current waveforms.

The sign of the mutual inductance can be specified in the following way. Suppose that the two circuits are connected in series. Then the total induced emf will be

$$-(L_1 + L_2 + 2M) \frac{di}{dt}$$

and the total reactance will therefore be

$$j\omega(L_1 + L_2 + 2M)$$

and will be greater than the sum of the reactances of the separate circuits when M is positive. A combination of two coils is said to be series aiding or series opposing, depending on whether they are connected so that M is positive or negative, respectively.

The Q -factor is used in describing the properties of an inductor. It is defined as

$$\frac{\omega L}{R} = \tan \phi$$

where ϕ is the phase angle of the complex impedance Z . An alternative term is the *power-factor* $\cos \phi$, particularly when the emphasis is on power dissipated rather than on the damping of tuned circuits.

An impedance Z can be represented by an equivalent circuit consisting of a resistance R in series with an ideal *series inductance* L . An alternative is to start with the admittance $Y = 1/Z$ and to represent this by the parallel combination of a resistance R' and a *parallel inductance* L' .

$$R = \frac{R'}{1 + Q^2}$$

$$L = L' \left(\frac{Q^2}{1 + Q^2} \right)$$

Note that, when Q is sufficiently large,

$$L' \simeq L$$

$$R' \simeq Q^2 R$$

Inductance Coil (Inductor). This is a device which is specially designed to possess inductance. The winding may have a ferromagnetic core composed of a dust-core material, metallic laminations or ferrite. An *air-cored* coil is one with no magnetic core.

Although it is the inductance which is of interest the influence of the electric field often cannot be neglected and causes the effect known as self-capacitance. At relatively low frequencies, the inductor will behave as if an equivalent lumped capacitance were shunted across its terminals. This simple equivalent circuit fails as the frequency is approached at which the apparent lumped capacitance would resonate with the inductance of the coil. The problem then becomes one of electromagnetic wave propagation, and the concept of inductance is no longer relevant. The effect of a fixed parallel capacitance C is to reduce the Q -factor to Q_c , where

$$Q_c = Q \left| 1 - \omega^2 LC \left(1 + \frac{1}{Q^2} \right) \right|$$

When Q is large, this becomes

$$Q_c \simeq Q(1 - \omega^2 LC)$$

The self-resonance effect is sometimes an advantage, e.g., in choke coils, where the object is to obtain a high impedance, irrespective of its phase angle. Generally however self-capacitance is an undesirable property, particularly in electrical networks in which the inductor forms part of a series resonant circuit.

The self-capacitance of a coil can be kept to a minimum by spacing the turns of the winding well

apart and also, in the case of a multi-layer winding, by ensuring that wires which lie physically close together always belong to adjacent parts of the winding so that the potential difference between them is relatively small.

The inductance of some types of coil can be calculated directly, without recourse to the Neumann equation. An example is the *toroidal coil*, i.e., one consisting of a uniform winding around a ring-shaped former. In this case the magnetic flux exists in a well-defined magnetic circuit and the inductance is given, very nearly, by

$$L = \frac{\mu_0 N^2 A}{l}$$

where N is the number of turns in the winding and A and l are, respectively, the cross-sectional area and the length of the magnetic circuit. The same formula also holds for a long, thin *solenoidal coil*. Corrections must be applied unless both the diameter of each turn and the radial depth of the winding are small compared with the length of the magnetic circuit for the toroid or the length of the coil itself for the solenoid.

If the toroidal former is replaced by one made of a magnetic material having a relative permeability μ , the inductance will be increased by a factor μ . For coils of other geometrical shapes, where some of the flux linking the winding may lie partly or wholly outside the magnetic core, the presence of the latter will increase the inductance by a factor called the *effective permeability* μ_e . This can never exceed μ and may be considerably smaller than μ .

The relative permeability of a ferromagnetic material is not a constant but is a function of the instantaneous flux density. This increases power losses and causes distortion of the current and voltage time-waveforms.

Power dissipation in a metallic core can be represented approximately by an equivalent series resistance R , where

$$\frac{R}{\mu_e f L} = c + h B_{\max} + ef$$

and B_{\max} is the peak flux density. The parameters c and h depend on the hysteresis properties of the core material. The parameter e is a measure of eddy-current losses in the core.

Ferrite materials are practically insulators; therefore eddy-current losses are negligible. For a ferrite, however, the relative permeability must be regarded as a complex quantity

$$\mu = \mu'(1 - j \tan \delta)$$

Both μ' and the dissipation coefficients $\tan \delta$ are functions of frequency.

The useful frequency range of coils with laminated cores is often limited by magnetic skin effect. This causes both the inductance and the Q -factor to start to fall as the depth of penetration of the electromagnetic field becomes comparable with the thickness of the laminations.

The depth of penetration d is given by

$$\frac{2}{d^2} = \omega \mu_0 \mu \sigma$$

where σ is the conductivity of the core material.

The inductance of a coil with a magnetic core is reduced if there is a superimposed unidirectional polarizing flux, caused for example by a dc current in the winding. This may be an unwanted effect or it may be used as a means of controlling the inductance.

Transverse air gaps are often introduced into the magnetic circuit. There are several reasons for this. An air gap reduces the flux density for a given magnetizing force, thus reducing the inductance of a given coil. The power losses are, however, reduced at a greater rate than the inductance so that the power factor is improved. The performance of the inductor is made less dependent on the magnetic parameters of the core material. The waveform distortion due to hysteresis is also reduced. An air gap may be used to prevent saturation of the core by the polarizing flux when the coil is required to carry a dc current.

If the inductance of a coil, with a closed magnetic circuit of length l , is L , an air gap of length g will reduce the inductance to L_g where

$$L_g = L \cdot \left[\frac{\mu}{1 + \mu(g/l)} \right]$$

As the gap ratio g/l is increased, the inductance tends to become independent of μ , particularly when μ is large. Note however that the formula assumes that the presence of the air gap does not change the geometry of the flux distribution; an assumption which is generally only justified for relatively small gap ratios.

Dust-cored or ferrite-cored coils, for which the core eddy-current losses are small, are often wound with stranded wire. This is done to keep the eddy-current losses in the winding low by ensuring that the individual conductor strands have diameters which are small compared with the depth of penetration of the electromagnetic field into the material of which they are made. At very high frequencies, where this condition cannot be met, solid wire is often used and the diameter of the wire is increased to compensate for the fact that only part of its cross-sectional area is effective as a conductor.

INERTIAL GUIDANCE*

Many modern spacecraft, aircraft, ships, and submarines are being designed to navigate by inertial guidance systems which use only sensed acceleration and vehicle turning rates for input information. Early inertial guidance systems, developed by the Germans during World War II, simply gyro-stabilized the airframe to the desired flight attitude, and used a single accelerometer to measure acceleration along the longitudinal (thrust) axis. When the integrated acceleration reached the desired injection velocity, the engines were cut off. Many unsophisticated systems still use this method.

Principles of Operation. Conventional inertial systems today are designed to provide a gyro-stabilized platform which is gimbal-mounted to permit unlimited vehicle motion without disturbing the stable element. On the stable element are mounted linear accelerometers to measure the two or three components of the vehicle's acceleration vector.

These components of acceleration are inputs to the computer (Fig. 1*), which solves the navigation equations - adding computed gravitation, integrating to find velocity, and integrating again to determine position:

$$\mathbf{R} = \int_0^t \int_0^t (\mathbf{A} + \mathbf{G}) dt^2 + \mathbf{V}_0 t + \mathbf{R}_0$$

where

\mathbf{R} - position vector

\mathbf{A} - non-gravitational acceleration vector (sensed acceleration)

* Illustrations from Parvin's "Inertial Navigation" (Principles of Guided Missile Design Series), Princeton, N.J., D. Van Nostrand Company, Inc., 1962.

\mathbf{G} - gravitational vector (calculated)

\mathbf{V}_0 = initial velocity vector (inserted)

t = time

\mathbf{R}_0 = initial radius vector (inserted).

This basic inertial navigation equation points up some of the basic characteristics of inertial systems:

(1) The inertial system must have initial position and initial velocity information (the two constants of integration).

(2) The accelerometer senses all non-gravitational forces (including thrust, drag, lift, and structural support).

(3) The gravitational field is not sensed; it must be calculated from known field equations.

Performance Characteristics. Inertial systems have several distinct characteristics not common to other systems. They

(1) give continuous rather than discrete information on acceleration, velocity, position, and vehicle attitude;

(2) require no signals from outside the system, so they are jamproof and can be used in vehicles launched in salvo;

(3) do not radiate signals, so they are difficult to detect in military applications;

(4) can be launched quickly but are most accurate when adequate prelaunch time is available for warmup, trim, and alignment;

(5) have errors that are a function of time rather than speed or distance;

(6) can provide by-product signals such as stabilization for flight control or radar antennas, velocity for mapping cameras, etc.

Error Characteristics. Systematic errors in pure inertial systems based on error in the knowledge of the gravity vector have a characteristic

FIG. 1. Function of the basic inertial system.

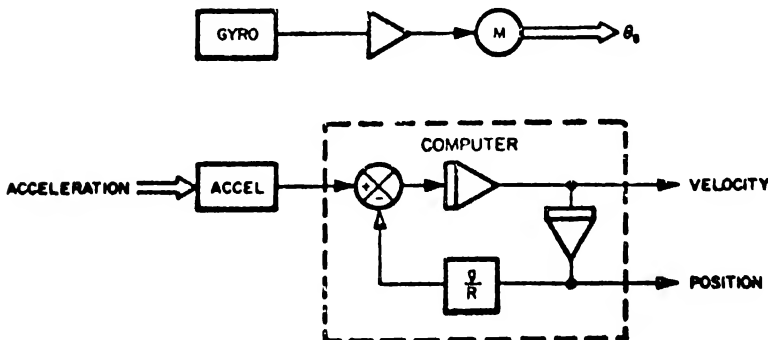

FIG. 2. Space-stabilized system block diagram.

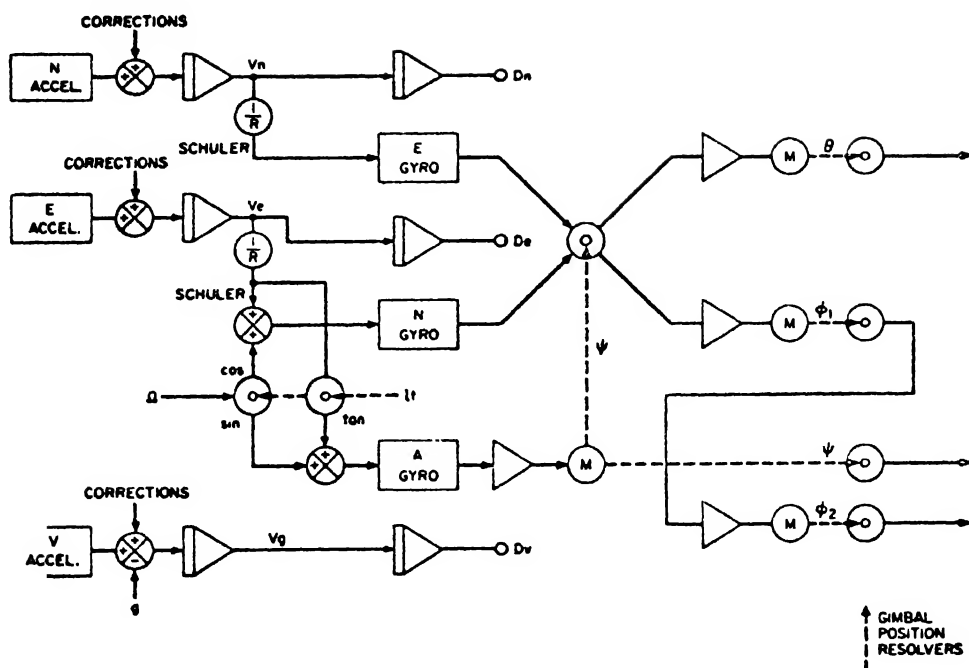

FIG. 3. Local vertical system block diagram.

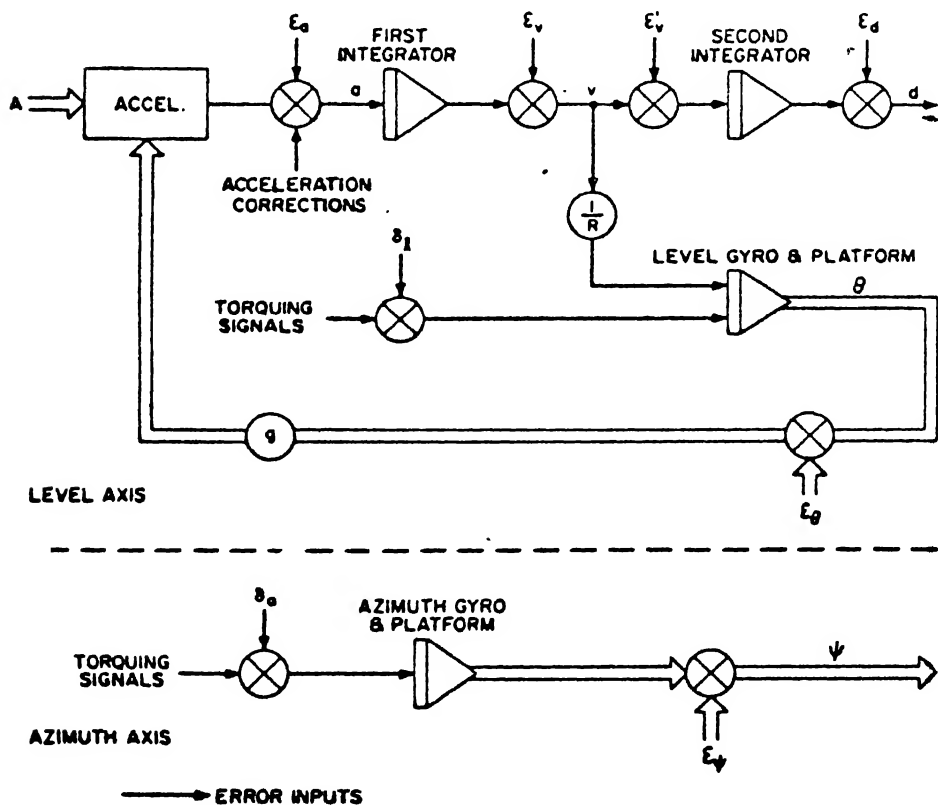

FIG. 4. Error inputs to local vertical system.

Schuler oscillation corresponding to orbital period (84.5 minutes at the earth's surface) in the horizontal components of the navigation position vector and an unstable exponential error in the local vertical component.

Basic System Mechanization. In the basic space-stabilized system (Fig. 2), the three accelerometer input axes are stabilized to any desired orientation in space by the GYROSCOPE (q.v.) stabilization control loops. A popular orientation for space vehicle launches is to have the Z axis vertical at time $t = 0$, the Z and X axes in the orbital or launch plane, and the Y axis orthogonal to Z and X . The gravitational force which starts out parallel to the Z axis is continuously computed as a function of the vehicle's position.

Local Vertical System. Another commonly used system mechanization is the local vertical system that maintains the Z axis vertical and the X axis north throughout flight for convenience in surface and air navigation. This requires biasing each of the gyros with a turning rate which

is a function of the earth's rotation rate plus the vehicle angular velocity around the curved earth's surface:

$$\omega_x = \Omega \cos lt + \frac{V_e}{R}$$

$$\omega_y = \frac{V_n}{R}$$

$$\omega_z = \Omega \sin lt + \frac{V_e}{R} \tan lt$$

where

- $\omega_{x,y,z}$ the computed bias signals to the x, y, z (north, east, and vertical) gyros
 Ω earth's sidereal rotation rate (15.041 deg/hr)
 lt local latitude of the vehicle
 $V_{e,n}$ vehicle east and north velocity
 R local earth's radius plus altitude.

In the local vertical system the accelerometers measure acceleration in a north, east, and vertical

FIG. 5. Classes of position errors.

reference system which rotates in space and therefore requires CORIOLIS (q.v.) corrections. The explicit gravitational calculation is avoided in the two level axes, and the vertical axis is often unnecessary in two-dimensional surface navigation. This mechanization is shown in Fig. 3.

Errors in Local Vertical Systems. The characteristic errors can be seen by analyzing the dynamic effect of errors entering the system at various points (Fig. 4). The position errors resulting from error inputs of assumed magnitude in each case are shown in Fig. 5. The total error in calculated position will be some combination of these.

Self-alignment. During the navigation mode the gyros hold the stable element to the desired attitude, but this attitude must be assumed before the navigation mode begins. This can be done during a self-alignment mode. The stable element is placed in a local level attitude by using information from the two level accelerometers, whose outputs are null when their input axes are level. Azimuth orientation information is derived from the east gyro, which senses no component of the earth's rate of rotation when oriented east. The self-level and gyrocompass alignment mode is shown in Fig. 6.

Strapdown Systems. In addition to the gimballed gyro-stabilized systems, there are several gimballess or strapdown configurations. One is the

relatively simple accelerometer, vehicle attitude control system first described. Another uses three accelerometers whose vehicle-referenced output pass through a dynamic coordinate transformation matrix in the computer. Three *rate* gyros provide the computer with vehicle attitude rate information necessary to compute the matrix. Although this approach eliminates gimbaling, it requires precision rate gyros and relatively large computer capacity to integrate attitude rate and provide a dynamic matrix.

A third gimballess system concept uses an inertial reference such as electrostatically suspended gyros to give vehicle *attitude* information to the computer for use in calculating the dynamic coordinate conversion matrix. Attitude rate integration is thereby avoided.

Steering Commands. An inertial navigation system primarily provides vehicle velocity or position. Guidance can be provided by the inertial system by supplying target location information to the computer, which then compares vehicle position with target position and calculates steering and (in the case of space flight) engine shutoff commands.

INFRARED RADIATION

The region of the electromagnetic spectrum between the wavelength limits 0.7 and 1000μ (7×10^{-7} and 1×10^{-1} cm) has become known as infrared radiation. The lower wavelength limit is set to coincide with the upper limit of the visible radiation region. Radiation of wavelength greater than 1000μ is generally thought of as the microwave spectrum. Both limits are arbitrary, and represent no change in characteristics as they are passed. Conventionally, the region between 0.7 and 1.5μ is called the *near infrared region*; that between 1.5 and 20μ , the *intermediate infrared region*; and that between 20 and 1000μ , the *far infrared region*.

For many applications, the location of infrared radiation in the spectrum is described by its wavelength in microns, μ , ($1\mu = 10^{-4}$ cm). In applications where the relative energy of the radiation is of interest, the *wave number*, σ , is used. The wave number is defined as the reciprocal of the wavelength, λ , in centimeters, and is expressed in units of cm^{-1} (called the *kayser*). This quantity is used more commonly than the frequency ν of the radiation, which is related to σ as follows:

$$\sigma = \nu/c \quad (1)$$

where c is the velocity of light.

Infrared radiation is produced principally by the emission of solid and liquid materials as a result of thermal excitation and by the emission of molecules of gases. Thermal emission from solids is contained in a continuous spectrum, whose wavelength distribution is described by the relation

$$I_\lambda d\lambda = \frac{2\pi c^2 h \epsilon_\lambda}{\lambda^5} \frac{1}{e^{hc/\lambda k T} - 1} d\lambda \quad (2)$$

where

I_λ = spectral radiant emittance of the solid into a hemisphere in the wavelength range from λ to $(\lambda + d\lambda)$

h = Planck's constant 6.62×10^{-27} erg sec

ϵ_λ = spectral emissivity

k = Boltzmann's constant $= 1.38 \times 10^{-16}$ erg $^\circ\text{K}$

T = absolute temperature of the solid emitter, $^\circ\text{K}$.

The spectral emissivity, ϵ_λ , is defined as the ratio of the emission at wavelength λ of the object to that of an ideal blackbody at the same temperature and wavelength. When ϵ_λ is unity, Eq. (2) becomes the Planck radiation equation for a blackbody.

The distribution of radiant emittance with wavelength for blackbody radiators at different temperatures is shown in Fig. 1. It is apparent from the Figure that blackbody radiation from emitters at temperatures below about 2000°K falls predominantly in the infrared region. An emitter which exhibits a constant value less than unity of spectral emissivity at all wavelengths is called a *gray-body* radiator. Most solid radiators show a general decrease in spectral emissivity with increasing wavelength in the infrared; however, over limited spectral ranges, many materials are approximately gray-body radiators. Radiators which approach the characteristics of ideal blackbodies can be made in the form of uniformly heated cavities. A relatively small aperture, through which the cavity can be observed, serves as the source of blackbody radiation.

FIG. 1. Spectral radiant emittance of a blackbody at various temperatures.

Infrared radiation is also observed as emitted from excited molecules of gases. Many of the energy transitions which take place in gases excited thermally or electrically result in radiation emission in the infrared region. Gaseous emission differs in character from solid emission in that the former consists of discrete spectrum lines or bands, with significant discontinuities, while the latter shows a continuous distribution of energy throughout the spectrum. The predominant source of molecular radiation in the infrared is the result of vibration of the molecules in characteristic modes. Energy transitions between various states of molecular rotation also produce infrared radiation. Complex molecular gases radiate intricate spectra, which may be analyzed to give

information of the nature of the molecules or of the composition of the gas.

The propagation of infrared radiation through various media is, in general, subject to absorption which varies with the wavelength of the radiation. Molecular vibration and rotation in gases, which are related to the emission of radiation, are also responsible for resonance absorption of energy. The gases in the atmosphere, for example, exhibit pronounced absorption throughout the infrared spectrum. The principal gases of the atmosphere, nitrogen and oxygen, do not absorb significantly in the infrared region. However, the lesser constituents, water vapor (H_2O), carbon dioxide (CO_2), and ozone (O_3), are responsible for strong absorption in the infrared. The absorption of radiation is so prevalent that those spectral bands in which relatively little absorption occurs are identified as *atmospheric windows*.

Solid and liquid materials show, as a rule, strong absorption in the infrared. There are, however, many solids which transmit well in broad regions of the infrared spectrum. Many materials, such as water and silica glasses, which show little absorption in the visible, are opaque to infrared radiation at wavelengths greater than a few microns. Many of the electrically insulating crystals, such as the alkali halides and the alkaline-earth halides, which transmit well in the visible, also are transparent to much of the near and intermediate infrared spectrum. Several of the semiconductor materials absorb strongly in the visible, but become transparent in the infrared beyond certain wavelengths characteristic of the semiconductor.

Detection of the presence, distribution and or quantity of infrared radiation requires techniques which are, in part, unique to this spectral region. The frequency of the radiation is such that essentially optical methods may be used to collect, direct, and filter the radiation. Transmitting optical elements, including lenses and windows, must be made of suitable materials, which may or

may not be transparent in the visible spectrum. Table I gives characteristics of several transmitting materials suitable for use in infrared optical systems. To avoid chromatic aberration, reflecting mirrors are commonly used in infrared optical systems to focus and deviate the radiation when broad spectral bands are observed. Filters for the infrared are designed and constructed like those for the visible, except for the choice of materials and, in the case of interference filters, the thickness of the layers.

The detector element for infrared represents the most unique component of the detection system. Photographic techniques can be used for the near infrared out to about 1.3μ . Photoemissive devices, comparable to the visible- and ultraviolet-sensitive photocells, are available with sensitivity also extending to about 1.3μ . The intermediate infrared region is most effectively detected by photoconductors. These elements, photosensitive semiconductors, are essentially photon detectors, which respond in proportion to the number of infrared photons in the spectral region of wavelength. This wavelength corresponds to the minimum photon energy necessary to overcome the forbidden gap of the semiconductor. A number of sensitive photoconductors are available with spectral cutoff at various wavelengths in the infrared. Photoconductors are employed as resistive elements, as photovoltaic $p-n$ diodes, or as photoelectromagnetic elements, according to the particular electrical advantage to be gained. All spectral regions from ultraviolet through visible, infrared, and microwaves, can be detected by an appropriately designed thermal element, which responds by being heated by the absorption of the incident radiation. In the infrared, thermal detectors take the forms of thermocouples, bolometers, and pneumatic devices. The thermal elements, in general, are not as sensitive or as rapidly responding as photoconductors in spectral regions where they both respond. However, the broad spectral response and uniform energy

TABLE I. INFRARED TRANSMITTING MATERIALS

Material	Useful Transmission Region (μ)	Refractive Index Near Transmission Peak	Special Characteristics
Optical glasses	0.3-2.7	1.48-1.70	Best for near infrared
Fused silica	0.2-3.5-4.5	1.43	Some types show absorption near 2.7μ
Arsenic trisulfide	0.6-12.0	2.4	A glass; subject to striations
Calcium aluminate	0.3-5.5	1.8	A glass; subject to attack by water
Sapphire	0.17-6.0	1.7	Single crystal, hard, refractory
Silicon	1.1-20	3.4	Low density; opaque to visible
Germanium	1.8-20	4.0	Opaque to visible
NaCl	0.2-15	1.52	Water soluble
KBr	0.21-27	1.54	Water soluble
LiF	0.11-6	1.35	Low solubility in water
CaF ₂	0.13-9	1.41	Insoluble
Thallium bromide-iodide (KRS-5)	0.5-40	2.38	Fairly soft; cold flows
AgCl	0.4-25	2.0	Soft; cold flows

sensitivity characteristics make them highly useful. Table 2 gives representative characteristics of several commonly used infrared detectors.

The most common application of infrared radiation is, of course, radiant heating. Solid radiators, such as hot tungsten filaments, alloy wires, and silicon carbide rods are employed extensively as sources of infrared to provide surface heating by radiation.

ployed to eliminate the effects of the short-wavelength radiation.

Optical-electronic devices of many varieties have been designed to determine the direction of weakly radiating remote objects by means of detection of their infrared emission. Military applications have been found which have been made possible uniquely by this technique. Missiles can be guided to their target by infrared detection

TABLE 2. INFRARED DETECTORS

Detector (operating temperature)	Region (μ)	Relative Detectivity at Peak	Time Constant (sec)	Special Features
PbS (295 K)	Visible-2.8	1	2×10^{-4}	Thin-film photoconductor
PbSe (195 K)	Visible 5.6	.06	2×10^{-4}	Thin-film photoconductor
InSb (77 K)	1-5.6	.5	2×10^{-7}	Photovoltaic crystal
Ge (Hg doped) (25 K)	1-16	8	10^{-6}	Photoconductor crystal
Ge (Cu doped) (5 K)	1-29	.5	10^{-8}	Photoconductor crystal
Ge (Zn doped) (5 K)	1-40	2	10^{-8}	Photoconductor crystal
Thermistor bolometer (295 K)	All	2.8×10^{-3}	$10^{-3} - 10^{-2}$	Flake of mixed oxides
Golay cell (255 K)	All	.02	1.5×10^{-2}	Pneumatic
Thermocouple (295 K)	All	.002	1.5×10^{-2}	Used in spectrometers

Infrared spectroscopy has become a powerful analytical tool in the chemistry laboratory. Organic molecules, in general, contain interatomic valence bonds which exhibit characteristic resonance frequencies which can be identified in the absorption spectrum of the material in gaseous form. Such information can be used to study the structure of complex molecules. It also serves in aiding the identification of the presence of known valence bonds in chemical analysis. Most absorption lines and bonds due to molecular vibrations fall in the frequency range 500 to 5000 cm^{-1} (wavelength range 2 to 20 μ). A large quantity of data has been gathered on the detailed absorption spectra of many gaseous materials. The characteristic spectra of many organic molecules are such that identification of the presence of the molecules, as well as the presence of particular radicals within the molecules, can be readily observed. Petroleum chemistry, for example, has been greatly aided by the application of infrared spectroscopy to the identification of many of the complex constituents in petroleum products.

Observation of infrared absorption spectra is carried out by means of an infrared spectrophotometer, in which the transmission of monochromatic radiation by a gaseous sample in a cell is compared with that of a blank cell, while the wavelength of the radiation is scanned through the spectral range of interest. Prism dispersing elements are usually used in the infrared, rather than gratings, because of the difficulty with the latter of separating the several orders in the wide spectral range covered. Far infrared spectroscopy is complicated by the omnipresence of background and scattered radiation of shorter wavelength emitted inside the instrument at room temperature. Special techniques of filtering must be em-

ployed to eliminate the effects of the short-wavelength radiation.

Such devices require the detection of low-level radiation in the intermediate infrared region. Optical lenses or mirrors are used to collect the observed radiation and concentrate it onto the sensitive infrared detector. High-gain, low-noise electronic amplifiers must be provided to increase the weak signal from the detector to a level which can be used to operate controls or displays, as demanded by the application. Optical filtering is applied in order to restrict the observed spectral region to one in which the target is effectively detected, with a minimum of interference from radiation from its background. The wavelength of detection is such that angular resolution capability, as set by diffraction, is much greater with infrared devices than that of radar devices. Detection of targets at great distances through intervening atmosphere is more effective in the infrared than in the visible because of the much lower atmospheric scattering in the infrared.

Detailed discussions of the characteristics, detection and applications of infrared radiation may be found in the references.

INTERFERENCE AND INTERFEROMETRY

Interference is the term used to signify a large class of phenomena in light, and interferometry is the technique of high-precision measurement based on these phenomena. Ordinarily rays of light crossing the same point in different directions do not interfere with each other; each ray is propagated as though it alone were present. However, there are certain interesting cases when these rays do interfere with each other; the interference may be destructive, as when they cancel each other's effect, or may be constructive, as when they reinforce each other. Interference is a consequence of light being propagated in the form of waves.

Young's Experiment. The classic experiment in interference is the one performed by Thomas Young in 1802. A source of light SL (see Fig. 1)

ripples be produced by a vibrating metal strip dipping in and out of the surface of water. A light floating body, say a leaflet, wobbles up and down with the same frequency as the vibrator. The ripples spread out in widening circles. If now another vibrator of the same frequency is brought near the first, the appearance of the ripples is completely changed. Along certain radial lines starting from the two vibrators, the water surface seems undisturbed; the leaflet does not move if placed along these lines. In between these lines the ripples have a very large amplitude.

At points equidistant from the two vibrators, i.e., along the perpendicular bisector of the line joining the vibrators, the waves from both arrive in phase. Both systems of waves tend to move the water up or down at the same time. The amplitude of the waves along this line is double that due to either of the systems of waves. At some other point sufficiently away from the perpendicular bisector, the crest of one system arrives at the same time as the trough of another, and thus the two systems cancel each other. Destructive interference occurs if the distances of the two vibrators from the point differ by $(n + \frac{1}{2})\lambda$, where λ is the wavelength and n is zero or an integer. Constructive interference occurs if the path difference is $n\lambda$.

An important condition for interference is that the two systems of waves are coherent, i.e., that they always have the same phase relation to each other. If the two slits P and Q in Young's experiment were illuminated by waves from two different sources, interference effects would not be observed. The reason is that waves produced by two sources would have no phase

FIG. 1. Young's experiment.

that is placed behind a narrow slit illuminates two other slits P and Q which are parallel and very close to each other. At some distance away is a screen which receives the light from the two slits. On the screen is seen a series of bright and dark fringes. If either of the two slits is covered, the fringes disappear, and the screen is almost uniformly illuminated. The combined effect due to the two slits is that at certain points there is no light at all, and at other points the brightness is four times that due to a single slit.

This puzzling phenomenon of light upon light producing darkness can be readily understood by considering the analogous case of ripples on the surface of water. Let a continuous series of

relation to each other. When the two slits are illuminated by different parts of the same wave front, they always arrive at any point beyond the slit with a constant difference in phase.

Theory. The mathematical expression for a progressive wave is

$$S = a \cos 2\pi\nu \left\{ \left(t - \frac{x}{v} \right) + \alpha \right\} \quad (1)$$

where S is the magnitude of the electric or magnetic field, also called displacement, at time t and distance x , a is the amplitude, ν the frequency, v the velocity, and α a term denoting

the phase. Due to the superposition of two waves, denoted by subscripts 1 and 2,

$$S = S_1 + S_2 = a_1 \cos 2\pi\nu \left\{ \left(t - \frac{x}{v} \right) + \alpha_1 \right\} + a_2 \cos 2\pi\nu \left\{ \left(t - \frac{x}{v} \right) + \alpha_2 \right\} \quad (2)$$

Both waves have the same frequency and velocity but different amplitudes and phases; x is measured from any arbitrary point. The displacement at $x = 0$ is given by

$$S = A \cos (2\pi\nu t + \alpha) \quad (3)$$

where A is the amplitude and α the phase of the resulting wave. By expanding the right-hand sides of Eq. (2) with $x = 0$ and Eq. (3), equating coefficients of $\cos 2\pi\nu t$ and $\sin 2\pi\nu t$, squaring and adding, one can see that

$$A^2 = a_1^2 + a_2^2 + 2a_1a_2 \cos(\alpha_1 - \alpha_2) \quad (4)$$

As $\cos(\alpha_1 - \alpha_2)$ varies between $+1$ and -1 , A varies between $(a_1 + a_2)$ and $(a_1 - a_2)$. If the amplitudes a_1 and a_2 are both equal to a , the minimum value of A is 0 and the maximum value is $2a$. Since the intensity is proportional to the square of the amplitude, the intensity at the maximum is 4 times that due to either wave. The condition for maximum brightness is: $\alpha_1 - \alpha_2 = 2n\pi$, which corresponds to a path difference of $n\lambda$.

Let R and S, Fig. 1, be the positions of the central fringe and the n th bright fringe below R. Let PQ = s , RS = x , and let D be the distance of the screen from the two slits.

$$PS^2 - QS^2 = \left\{ D^2 + \left(x + \frac{s}{2} \right)^2 \right\} - \left\{ D^2 + \left(x - \frac{s}{2} \right)^2 \right\} = 2xs$$

$$PS - QS = 2xs / (PS + QS) \approx 2xs / 2D$$

since $PS + QS$ is very nearly equal to $2D$.

$$PS - QS = n\lambda, \text{ so that } \lambda = \frac{1}{n} \frac{xs}{D} \quad (5)$$

Equation (5) formed the basis for the first experimental determination of the wavelength of light.

Young's experiment in its original form was difficult to perform and failed to carry conviction when the results were first published. If $s = 1$ mm, $D = 2$ meters, the distance between successive

fringes for sodium yellow light ($\lambda = 5.89 \times 10^{-5}$ cm) is only 1.2 mm. The illumination is too poor, the fringes are too close, and two fine slits at 1 mm distance are difficult to produce. The controversy as to whether light is propagated as corpuscles or waves had existed for over a century and a half. Francesco M. Grimaldi, who is regarded as the founder of the wave theory of light, in his book, *Physico-Mathesis de Lumine, Coloribus et Iride*, published in 1665, described several experiments on diffraction and interference of light, and presented the rudiments of a wave theory. Newton discussed several diffraction effects in his *Opticks*, published in 1708; he threw his weight heavily on the side of the corpuscular theory of light. Experiments more convincing than those of Young were needed to overthrow a theory based on Newton's authority. Between 1814 and 1816, Fresnel introduced two better methods of producing interference fringes, he also gave a more complete theory of the formation of the fringes, based on the hypothesis of secondary wavelets which was first developed in 1678 by Huygens. Huygens' hypothesis was that every point on a wave front acted as the source for a secondary train of waves and that the envelope of these secondary waves determined every successive position of the wave front.

The two improved experimental arrangements introduced by Fresnel were the bimirror and the biprism. These solve the difficulty of obtaining two slits sufficiently narrow and close to each other. In the bimirror arrangement, light from a narrow slit is reflected by two plane mirrors inclined at a small angle to each other. Thus the two slits are replaced by the two images of a single slit, and the distance between these can be adjusted by changing the angle between the mirrors. In the biprism arrangement, two small angle prisms joined at their base each produce a small deflection of the light emerging from a single slit, and thus cause two sets of coherent waves to be superposed. A single mirror may also be used as devised by Lloyd to produce interference between wave trains produced by a slit and its image.

Applications of interference effects. There are many interesting applications of the principle of interference. Refractometers based on interference effects are used to measure small changes in the refractive index of transparent media (see REFRACTION). In the Rayleigh refractometer (see Fig. 2), light from a linear source S, made parallel by a lens L_1 , is split into two beams by two fairly wide slits, and then made to pass through two similar tubes T_1 and T_2 . After transmission

FIG. 2. Rayleigh refractometer.

through the tubes, the two beams are brought to a common focus by another lens L_2 . If the two tubes contain transparent media of the same refractive index, say the same liquid, the center of the fringe pattern is formed on the axis of the instrument. If the refractive index of the liquid in one of the two tubes is changed, as for example by introducing a solvent, the fringes shift across the focal plane of the viewing lens. By counting the number of fringes which cross a reference line, the equivalent path difference and hence the change in refractive index can be calculated. Compensator plates M_1 and M_2 , which restore the fringe pattern to its original position, are convenient devices for counting the fringe shift.

Michelson's method of measuring stellar diameters is another application of interference. A beam mounted over the entrance aperture of a large telescope carries four mirrors as shown in Fig. 3. The arrangement is similar to that of

FIG. 3. Stellar interferometer.

Young's experiment, with the mirrors M_1 and M_2 as the slits and the star as the source. The diffraction image of the star is crossed by interference bands if M_1 and M_2 are relatively close to each other. As the distance between them is increased, the fringes become less distinct and finally disappear. This is due to the fringe pattern from one half of the star being completely canceled by that from the other. If the distance between M_1 and M_2 for disappearance of the fringes is s , r is the distance of the star, d its diameter, and λ the wavelength of light; $d/r = 1.22\lambda/s$. The first star to be measured by this method was Betelgeuse, for which the bands disappeared at $s = 306.5$ cm. Substituting values 5.75×10^{-6} cm for λ , and 1.712×10^{20} cm for r , as determined from the parallax of Betelgeuse, the diameter of the star is found to be 3.918×10^{13} cm, which is 31 per cent greater than the diameter of the earth's orbit around the sun. Several other near stars of large size have since been measured by the same method.

Thin films of transparent media produce striking interference effects, as for example,

when a few drops of gasoline are spilled over a wet pavement. The two wave trains which interfere in this case are those reflected from the upper surface of the oil film and from the water-oil interface. The colors of butterflies' wings and sea shells have a similar origin. The so-called Newton's rings are produced by the air film between two partially reflecting, spherical surfaces. The optical quality of a glass surface can be tested by causing interference fringes between it and a standard test plate of high optical quality. The fringes are analogous to contour lines in geographical maps, each new fringe indicating deviation from true flatness by half a wavelength.

Interferometers. Interferometers are instruments of high-precision measurement based on the principle of interference. A beam of light is divided into two or more beams by partial reflection and transmission, and these are recombined after they have traveled different path distances. Of the many different types of interferometers, only two which are widely used will be described here, the Michelson interferometer and the Fabry-Perot interferometer.

The Michelson interferometer is shown schematically in Fig. 4. Monochromatic light from an

FIG. 4 Michelson interferometer.

extended source is collimated by a lens L_1 and falls on the beam splitter M of which the hind surface partially reflects half the intensity upward and transmits the other half. The two halves of the beam are returned by the mirrors M_1 and M_2 , and the interference pattern is viewed in the focal plane of the lens L_2 . C is a compensator plate similar to M , which gives the beam from M_2 an extra path equal to that traveled by the other beam in the beam splitter. The form of the fringes depends on the adjustment of the two mirrors M_1 and M_2 . If they are not quite at right angles to each other, and the difference in path of the two beams is small, the image of M_2 in M forms

a thin wedge with the front surface of M_1 . The fringes are straight and parallel to the apex of the wedge. If the difference in path is large, the two mirrors should be adjusted so that the image of M_2 in M is exactly parallel to M_1 . In this case, the fringes are circular. Each circle is due to pencils of light which have a constant inclination to the axis of the lens L_1 .

Two of the applications of the Michelson interferometer are of historic importance: the standardization of the meter in terms of the wavelength of light and the Michelson-Morley experiment for the drift of ether. If one of the two mirrors is moved parallel to itself, the pattern of fringes shifts across the field of view. The displacement of the mirror for each fringe shift is $\lambda/2$. This method was first used by Michelson and Benoit in 1892 for comparing the red line (6438Å) of cadmium with the International Prototype Meter which is kept in Paris, France. More precise measurements of the meter in terms of the wavelength of light have since been

moved parallel to itself at a very constant rate. The variation of intensity over a small area at the center of the ring system at P is measured by an infrared detector. If the source were strictly monochromatic, the output signal of the detector would vary sinusoidally with time. The displacement of the mirror between successive maxima is half a wavelength. With a composite source as input, the output is the sum of a large number of sine functions, each of them being due to the energy in a narrow wavelength band of the source. A Fourier transform of the output signal, as may well be obtained with the aid of a digital computer, gives the spectral energy distribution of the source. The compactness of the instrument is a special advantage compared to infrared prism monochromators, and hence several designs of the interferometer spectrophotometer have been developed for use in satellites and space probes.

The Fabry-Perot interferometer (see Fig. 5) consists of two parallel plates of glass or quartz.

FIG. 5 Fabry-Perot interferometer.

made by other observers. Since the wavelength of light is a more reliable standard and can be measured with greater accuracy, it was judged desirable to replace the standard meter by a suitable spectral line as the standard of length. The International Commission of Weights and Measures formally adopted in 1960 the orange-red line of krypton 86 as the standard and defined the meter as exactly 1 650 763.73 wavelengths in vacuum of this line.

The MICHELSON-MORLEY EXPERIMENT of 1887 was an attempt to measure the speed of the ether "wind" past the moving earth. If one arm of the interferometer is in the direction of the earth's motion relative to the ether and the other at right angles to this motion, the relative path difference between the two beams of light is nearly Lv^2/c^2 , where L is the length of each arm, v is the velocity of the earth and c is the velocity of light. By floating the interferometer in a pool of mercury and rotating it through 90°, a fringe shift corresponding to twice this path difference should be observed. Accurate experiments showed that the fringes did not shift. This negative result served as the basis for the theory of relativity.

A recent application of the Michelson interferometer is for spectrophotometry of composite sources. The method is especially applicable for the infrared range. One of the two mirrors is

The inner surfaces are optically flat and semi-silvered. Light from an extended source is made parallel by a lens L_1 , passes through the interferometer and is focused by another lens L_2 . A system of circular fringes is observed in the focal plane of L_2 . The path of an oblique ray of light in between the two plates is shown in Fig. 5. Interference takes place between the directly transmitted ray and the rays that undergo one or more reflections between the plates. A high degree of wavelength resolution is the main advantage of the Fabry-Perot interferometer. In a typical case of 1-cm separation of plates and 90 per cent reflectance, wavelength resolution is over a million; i.e., two wavelengths 0.005Å apart at 5000Å will give completely distinguishable ring systems. By increasing the reflectance of the plates or the separation between them, the wavelength resolution can be increased to any desired degree. Laser beams which give highly coherent single wavelengths permit plate separation of over a meter. Extensive use has been made of the Fabry-Perot interferometer for precision measurement of wavelengths of spectral lines.

INTERNATIONAL GEOPHYSICAL YEAR AND INTERNATIONAL YEARS OF THE QUIET SUN

It has been recognized for some time that the sun, ultimate source of practically all of the energy utilized on earth (the only current exception being the relatively small amount of power produced by nuclear fuels), influences many earthly phenomena. Aside from the obvious solar control of the weather through visible and invisible light—electromagnetic radiation—continuously emitted by the sun, other less well-understood effects occur. For example, the so-called earth storm (not to be confused with a weather disturbance near the ground) results from the arrival not only of radiation but also of matter—streams of electrically charged particles—spewed out by the sun following violent eruptions or flares in the chromosphere, just above the sun's "surface" (photosphere).

A multitude of geophysical effects arises from the interactions of these radiation and particle fluxes with the upper reaches of the earth's atmosphere, manifesting themselves as phenomena such as magnetic storms, radio disturbances, and auroral displays. The frequency of occurrence of these transitory happenings in the upper atmosphere waxes and wanes as the level of solar activity changes during the well-known sunspot cycle.

Taken together, the International Geophysical Year (IGY) and the International Years of the Quiet Sun (IQSY) mark the beginning and end points of a tremendously significant study of the extremes of the solar cycle. The first part, IGY (1957–1958), took place at the peak of sunspot activity (it was not only peak for the average eleven-year cycle—but, in intensity, has probably not been matched at least since Galileo first observed sunspots in the early seventeenth century). IQSY (1964–1965) is the follow-up aimed at catching the myriad interrelated phenomena of sun, space, and earth at the sun's nadir of activity. But the current enterprise is not to be regarded as a small-scale repetition of its illustrious predecessor. On the contrary, in the fields

that it embraces, the level of the effort far exceeds that which it was possible to attain even as recently as seven years ago. In a sense, IGY really set the stage for IQSY.

Scientific Objectives. The broad objective of IGY was to study every aspect of the earth as a planet, including its environment. Consequently, in addition to investigating the properties of the earth's interior (seismology, latitude and longitude, and gravimetry) and studying its surface characteristics (oceanography and glaciology), the program embraced observations in and beyond the earth's atmosphere, including investigations of sun-earth relationships (meteorology, nuclear radiations, geomagnetism, ionosphere, aurora and airglow, cosmic rays, and solar activity). And, to increase basic knowledge about the solar influences acting upon the earth, IGY was planned to cover a period at or near solar maximum (see also GEOPHYSICS and SOLAR PHYSICS).

IGY was *not* the first international effort, however. There had been similar undertakings before: The First International Polar Year, 1882–1883, and the Second International Polar Year, 1932–1933. The recent enterprises are distinctive for other reasons; they involve the first extensive *in situ* probing of the earth's envelope, thanks to the subsequent development of rockets and, most recently, of satellites.

One motivation for IQSY was to utilize to the fullest extent the remarkable new technology and facilities, spawned by IGY, that have now matured to a previously undreamed of stage of development. Not only are vehicles now available for conducting highly sophisticated experiments in space, but other new techniques have added new dimensions greatly extending the possibilities which existed even as recently as seven years ago. Furthermore, logistic capabilities have materialized that make it feasible to carry out large-scale programs in crucial but previously inaccessible regions of the globe.

Antarctica, as a locale for research, deserves special mention. Not only is it important for studying upper atmosphere phenomena on a global scale, but it is vital in the conduct of all studies of upper atmosphere phenomena. The key to the preeminent role of the polar regions in the upper atmospheric research is the terrestrial magnetic field. Electrically-charged particles approaching the earth can, unless they are endowed with higher energies, arrive only near the geomagnetic poles. Consequently, the lower energy protons and heavier atomic nuclei that are sometimes produced by the sun can be observed only in these regions. Similarly, auroral effects, as well as other phenomena relating to magnetic lines of force that extend to very great distances from the earth's surface, can be observed only near the geomagnetic poles.

The purpose of IQSY is threefold. Some of the studies that are being conducted are feasible, or are best undertaken, only at the time of solar minimum. Others are concerned with observing in detail isolated solar events, uncomplicated by

the superposition in time of a number of concurrent outbursts. Finally, some investigations are providing data characteristic of solar minimum conditions for comparison with those obtained previously during solar maximum.

Actually, at sunspot minimum, solar outbursts do not cease completely, but when they do occur, their effects can be observed under relatively "clean" conditions, free from confusing interferences. Hence, the entire sequence of events associated with a single outburst can be followed. Furthermore, smaller effects, previously lost in the high-level background of activity, are discernible. Thus, many IQSY projects are taking advantage of this period to make observations with greatly increased "amplification".

The IQSY Program. The IQSY program is organized in eight disciplines, although in most cases there are overlapping interests, and no sharp boundary line is drawn. The disciplines involved are the following:

Meteorology. The upper 10 per cent of the atmosphere is emphasized. This is the region in which solar influences are propagated to the lower atmosphere. Every available technique, including the use of rockets and satellites, is being utilized for determining the meteorological parameters that are relevant to atmospheric energy transfer (see METEOROLOGY).

Geomagnetism. A detailed study of the earth's main magnetic field is being conducted. Magnetic disturbances, which are related to many geophysical phenomena, are observed by an extensive network of ground-based observatories. Rockets and satellites are also providing important information extending through the magnetosphere, the magnetopause (termination of the earth's magnetic field), and the transition region between the interplanetary and terrestrial fields (see GEOPHYSICS).

Aurora. Instrumentation carried aloft by balloons, rockets, and satellites is being employed to determine the characteristics of aurora-producing particles and the mechanisms of particle acceleration and precipitation, supplementing studies based upon observations from the ground (see AURORA AND AIRGLOW).

Airglow. Airglow emissions yield important information about the structure and chemical composition of the upper atmosphere. The geocorona, a ring of hydrogen that girds the earth and is detectable through the Lyman- α light that it emits, is of special importance because of its response to the flow past the earth of the solar wind (see AURORA AND AIRGLOW).

Ionospheric Physics and Radioastronomy. The ionosphere, well known because of its association with radio transmission, is being probed by a variety of means both from above and below. Observations at conjugate points (opposite ends of a magnetic line of force) on the earth's surface are also being made. Advantage is taken of the decreased opacity of the ionosphere for extending radioastronomical observations of galactic and extragalactic sources to lower frequencies, and radio emissions from the planets are also being

studied (see IONOSPHERE and RADIOASTRONOMY).

The Sun and the Interplanetary Medium. Constant surveillance of the sun is being maintained to detect disturbances over a broad spectrum of wavelengths. Solar structure is being investigated with new techniques, and magnetic fields originating at the sun and carried into space by the corpuscular radiation which constitutes the solar wind are being measured directly. The interplanetary medium is being probed both by direct and indirect methods (see SOLAR PHYSICS and SPACE PHYSICS).

Cosmic Rays and Geomagnetically Trapped Radiation. The lower energy cosmic rays, shielded by clouds of magnetized plasma emitted by the sun, can be observed only at solar minimum. Various characteristics of both the galactic cosmic rays, and of solar-produced particles, are being investigated by a variety of means (see COSMIC RAYS and RADIATION BELTS).

Aeronomy. *In situ* measurements with rocket and satellite vehicles are adding to our knowledge of the physics and chemistry of the upper atmosphere. By obtaining a complete description during quiet conditions, a base line will be provided for comparison with events occurring in association with solar disturbances (see PLANETARY ATMOSPHERES).

In the United States, a Committee of the National Academy of Sciences, the U.S. Committee for IQSY, is responsible for development of the program. The members are: R. G. Athay (solar activity), J. W. Chamberlain (aurora and airglow), H. Friedman (aeronomy), J. Kaplan (member-at-large), W. W. Kellogg (meteorology), P. Meyer (cosmic rays), H. Odishaw (ex officio), M. A. Pomerantz (chairman), E. Dyer (executive secretary), M. A. Tuve (ex officio), E. H. Vestine (geomagnetism), and A. H. Waynick (ionospheric physics). Within the government, the National Science Foundation was designated by the president as the responsible agency for coordinating and implementing the program, and for correlating regular activities of the government that relate to the program. Robert Fleischer, of the Office of Atmospheric Sciences, is NSF coordinator for IQSY.

The Special Committee for IQSY, established by the International Council of Scientific Unions (ICSU), with a Secretariat in London, formulated and is executing the detailed plans of this great cooperative venture in which scientists of seventy-one nations are participating. The Bureau is comprised of the following members: W. J. G. Beynon, president; M. A. Pomerantz, N. V. Pushkov, and G. Righini, vice presidents; and C. M. Minnis, secretary.

IONIZATION

Ionization is the name given to any process by which a net electrical charge may be imparted to an atom or group of atoms. In the case of liquid solvents, molecules or ionic salts become dissociated to form positive and negative ions. This ionization process is known as *electrolysis*, and the name *electrolyte* is given to the solute or to the conducting solution. The study of electrolysis is embodied in the subject of *electrochemistry*. Of great interest in recent years has been the study of ionized gases. Rockets, hypersonic flight, and space physics have spurred investigations of plasmas, shock waves and high-temperature chemical processes arising in a variety of terrestrial and celestial phenomena. Indeed, ionized gases make up a major portion of all matter in the universe. Our chronic need for new energy sources has transformed the speculation of a controlled thermonuclear fusion reaction into one of the greatest research efforts in history. These and other considerations have induced a vigorous growth in the study of ionization phenomena.

Electrolytes. The degree of ionization found in electrolytes is highly variable and depends upon the solute, the solvent, and the interaction between them. *Weak* electrolytes, such as many organic compounds, are solutes which are barely dissociated into ions except in the limit of infinite dilution. *Strong* electrolytes are highly dissociated at any concentration. Ions formed in solution may bear one or several electronic charges. The *electrochemical equivalent weight* is the atomic weight divided by the number of charges carried by the ion. If electrodes are placed in an electrolyte and a current flows in the external circuit, the ions with positive charges, called *cations* (cathode + ions), will migrate toward the negative electrode (cathode). Those ions possessing a negative charge (*anions*) will migrate to the positive electrode (anode). The ions arriving at the cathode are neutralized by the acquisition of electrons; the atoms or molecules thus formed may then be evolved as a gas or retained as a deposit on the electrode. The cations are said

to undergo *reduction*. Likewise, the anions experience a loss of electrons at the anode; this process is called *oxidation*. The quantity of electricity required to deposit one gram equivalent is called the faraday, in honor of Michael Faraday (1791-1867). Based on the physical scale of atomic weights, the faraday is numerically equal to 96,520 coulombs per equivalent.

As for any solid conductor of uniform cross sectional area A and length l , the electrical resistance R of an electrolyte is given by $l/\kappa A$. The conductivity κ is independent of geometrical shape and size, and bears the units $(\text{ohm cm})^{-1}$. Of greater importance in the study of electrolytes is the *equivalent conductivity*:

$$\Lambda = \kappa/C$$

where C is the concentration of the solute in equivalents per cubic centimeter. Plots of Λ as a function of concentration show very different behavior for weak and strong electrolytes. The latter exhibit a limiting value of Λ as C diminishes to zero, while the weak electrolytes do not. Such behavior provides insight into the nature of the ions, their mobilities and their interactions with the solvent material.

Formation of Gaseous Ions. Studies in 1895 by J. J. Thomson of the effects of newly discovered x-rays on gases marked the beginning of a series of experiments which established the existence of the electron and clarified many questions on the nature of atomic structure.

Just as in electrolytes, both positive and negative ions may exist in an ionized gas. In addition to the ions, the presence of free electrons may profoundly influence the character of the gas. Negative ions may be formed by the attachment of free electrons to a neutral atom or molecule, by the dissociation of a neutral molecule into positive and negative fragments, or by electron transfer upon collision of two neutral atoms or molecules. Positive ions may be formed by dissociation, charge transfer, neutral-particle or electron collisions, or by photoabsorption (the absorption of electromagnetic radiation). Still another mechanism for the formation of ions is the emission of a nuclear particle, such as beta decay. Several of these processes are discussed below.

Photoionization. Photoabsorption leading to excitation and ionization is of interest because of its significance in astrophysics and geophysics. The ionosphere is constituted of molecular and atomic ions which result from the absorption of solar ultraviolet and x-radiation. The frequency ν of the electromagnetic radiation giving rise to ionization must satisfy the relation $h\nu \geq V$, where h is Planck's constant and V is the *ionization potential*. The latter is defined as the energy required to remove completely an electron from an atom or molecule in the ground state, leaving the resulting ion in its lowest state. Photons having energy less than V may be absorbed by atoms or molecules, giving rise to excitation of internal states or perhaps molecular dissociation, or both.

Many laboratory investigations of photoabsorption have been performed. One type of experiment requires the measurement of the absorption coefficient, α , of a photon beam:

$$I = I_0 e^{-\alpha x}$$

in which I_0 is the initial intensity of the beam and I is the intensity after the beam has traversed a distance x in the absorbing gas. The absorption coefficient may then be studied as a function of photon energy (i.e., wavelength). It can be expressed in terms of a microscopic cross section for absorption or for ionization as a function of incident wavelength. This cross section curve for photoionization usually exhibits a sharp peak at the ionization threshold. Only a single, outermost electron is ejected from an atom which absorbs an ultraviolet photon. An x-ray photon generally will eject a more tightly bound electron from one of the atom's inner shells.

Other types of experiments utilize photoionization to study the deionization process for the ions thus formed. Of major importance are such processes as electron-ion recombination:

and ion-ion recombination if both charged species are ions.

Ionization by Heavy-particle Collisions. By heavy particles is meant both atoms and molecules and their ions, ranging in mass from the hydrogen atomic ion (proton) to very heavy molecular systems of large atomic number. When two heavy particles collide with sufficient energy, one or more electrons may be ejected from either or both particles. In experimental work, the *target* molecules or atoms are in the form of a low-density gas having an energy corresponding to room temperature and usually negligible compared to the energy of the projectile particles. The latter are usually obtained through ionization of a selected gas in an ion source, and acceleration through a large electric potential difference E . Regardless of the mass of the projectile particles, their kinetic energy will be equal numerically to E electron volts, if the potential difference E is in volts and if the particles carry but one elementary charge. One electron volt (eV) is equal to 1.6×10^{-12} erg.

If a beam thus formed with an intensity of B particles per second is incident on a target chamber of area A containing N target particles as a low-density gas, the electron ionization current i which is released is given by

$$i = BN\sigma/A \text{ electrons/sec.}$$

This equation defines the effective ionization cross section σ . For energies at which multiple ionization is improbable, σ approaches the cross section for singly charged ions. Often the distinction is made between ionization of the target particle and the beam particle. Ionization of the latter is referred to as stripping.

In the quantitative description of heavy-particle collisions, one usually introduces the concept of

the (a) laboratory and (b) center-of-mass (CM) coordinate systems. The laboratory system is used to describe the motion of the particles as would be viewed by an observer standing at rest in the laboratory. The origin of the CM system moves with the center-of-mass of the two-particle system. If m and M are the masses of the projectile and target particles, the former moving with a velocity v much greater than the target velocity, the center-of-mass velocity V_c is

$$V_c = mv/(m + M) = \mu v/M$$

The latter relation defines μ , the reduced mass. The kinetic energy in the CM system is $\frac{1}{2}\mu v^2$, which is the projectile energy multiplied by $M/(M + m)$. For the case in which target and projectile are identical, the kinetic energy in the CM system is half that of the projectile. Using the law of conservation of linear momentum, one may show that the kinetic energy in the CM system is the maximum energy available for excitation and/or ionization.

Collisions in general are classified as (a) elastic in which no changes in internal states occur, and for which kinetic energy is conserved, and (b) inelastic, in which a part of the kinetic energy is converted to internal energy. A *superelastic* collision is one in which internal energy is transformed into kinetic energy. Because of the extreme complexity encountered in quantum-theoretical calculations of ionization cross sections for heavy-particle collisions, very little progress has been made in this important area of collision theory.

Ion-neutral collisions may give rise to free electrons, or simply *charge exchange* which, in its simplest form, is expressed by the equation.

The neutral particle B has been ionized, but the electron has transferred to the incident ion, neutralizing it. The energy ΔE released in this process is the difference between the ionization potentials of the neutral particles A and B . For the case in which A and B are identical, $\Delta E = 0$ and the process is called *symmetric resonant* charge transfer. At low ion beam energies, this transfer proceeds with a large cross section.

Ionization by Electron Impact. Of great importance in atomic physics is the ionization produced by collimated beams of electrons incident on heavy particles. Whether the target particles are atoms or molecules, the ionization is usually by the removal of single electrons from the outermost shell, as in photoionization. As a function of the incident electron energy, the ionization cross section rises rapidly from zero for energies just below the ionization potential and increases to a maximum value in the neighborhood of 50 to 100 eV; thereafter it decreases slowly and monotonically with increasing electron energy. Since an electron with a given energy travels at much higher speed than does a heavy projectile of the same energy, the electron collision induces a much more rapid perturbation on the target's

orbital electrons. Thus, a larger ionization cross section at low energies is to be anticipated.

Much of the definitive work on electron impact ionization was performed in the 1930's by Tate, Smith, and Bleakney (cf. reference 4).

Collective Processes. If, as in a glow discharge, a large number of charged particles are created, the collective interactions of these particles with each other and with external fields may permit the charged fluid to exhibit very unusual and distinct properties. An ionized gas possessing both positive and negative charges is called a *plasma* if the distance over which the gas can have an appreciable departure from charge neutrality is small compared to the dimensions of the gas. This distance is described by the *Debye-Hückel radius*, a quantity borrowed from the theory of strong electrolytes, which characterizes the decay of the shielded Coulomb potential surrounding the ionized particles of the fluid. If the charge neutrality in a plasma is disturbed in some manner, the electrons will be forced to oscillate about their equilibrium positions in simple harmonic motion with a frequency characterized by the electron density. Longitudinal oscillation of the ions and electrons as a whole constitutes another type of motion called *ion-acoustical waves*. *Hydro-magnetic waves*, which appear in the presence of a magnetic field, are still another form of motion not observed in an unionized medium. The description of such phenomena goes beyond the scope of the ionization process.

IONOSPHERE

The ionosphere is the gas of charged, thermal particles which forms a fraction of the earth's atmosphere between about 50 km above the surface and the outer limit of the atmosphere. The term "ionosphere" is also used to mean the atmospheric region in which the ionosphere lies. Other planets have ionospheres too, although,

of course, our knowledge of them is still almost entirely theoretical. The ionosphere is also sometimes defined as "the part of the earth's upper atmosphere where ions and electrons are present in quantities sufficient to affect the propagation of radio waves." Indeed, the ionosphere has been studied primarily by its effects on radio waves, although *in situ* measurements from rockets and satellites are playing an increasingly important role. This definition also emphasizes the practical importance of the ionosphere: it refracts and reflects radio waves and so makes possible beyond-the-horizon radio propagation.

The ionosphere is divided into six regions or layers which are called, from bottom to top, the C, D, E, and F regions, the heliosphere, and the protonosphere. The F region is subdivided into the F1 and F2 layers, and the C region was, until recently, considered to be the lower part of the D region. These regions or layers are more or less identifiable on a graph of electron concentration vs. height, but they are properly defined in terms of the processes by which they are formed, and not by the height ranges in which they lie. Nevertheless, their typical heights are useful. The lower limit of the C region is conventionally 50 km. The boundary between the C and D regions is at about 70 km; between the D and E regions, at about 90 km; between the E and F regions, at 120 to 140 km, and between the F1 and F2 layers, at about 200 km. The heights of the boundaries between the F region and the heliosphere and between the heliosphere and the protonosphere are poorly observed, but they are known to increase with increasing atmospheric temperature. Thus, the lowest heights, which may be as low as 500 km, occur at night and during periods of minimum solar and geomagnetic activity. The highest heights, which occur during the day, and during periods of maximum solar and geomagnetic activity, may be very much greater. The outer limit of the protonosphere (the magnetopause), which is also the outer limit of the ionosphere and the earth's atmosphere, is always at least several earth radii from the earth.

In the C and D regions, the positive ions are probably mostly NO^+ , and the negative charge is carried partly by electrons, partly by O_2^- , and partly by some other species of negative ions. In all of the higher regions, the negative charge is carried almost entirely by electrons. In the E and F1 regions, the positive ions are mostly O_2^+ and NO^+ ; in the F2 layer, O^+ ; in the heliosphere, He^+ ; and in the protonosphere, H^+ (protons). Throughout, the ionosphere is very nearly electrically neutral; i.e., the total positive and negative charge concentrations are very nearly equal.

Typical values of the electron concentration at noon are: C region, 10^2 electrons/cm³; D region, 10^3 to 10^4 ; E and F1 regions, 10^5 ; F2 layer, 10^6 ; heliosphere, 10^4 ; protonosphere, 10^4 to 10^5 . At night the concentrations in all of the regions tend to be smaller; in the D and E regions, by a factor of 10. In all of the regions, the electron

concentration has complex dependences on the time of day, season, latitude, and solar and geomagnetic activity. The variations of the F2 layer are particularly large and well-observed: its concentration ranges from 10^4 to 10^7 electrons/cm³ under different conditions.

Superimposed upon the rather smooth ionization concentration of the ionospheric regions are many kinds of spatial irregularities, which are loosely grouped into "Sporadic E" in the E region and "Spread F" in the F region. Sporadic E is usually found in thin horizontal sheets. One of the commonest types consists of a slab only a few hundred meters thick and tens of kilometers in horizontal extent in which the electron density may be as much as a factor of ten larger than in the ambient E region. In the F region, on the other hand, the irregularities are filaments aligned along the lines of force of the earth's magnetic field. They are from a few meters to a few kilometers across and they extend along the field lines from the lower F2 region indefinitely upwards, even to the opposite hemisphere. The individual filaments appear to be arranged in east-west sheets. The electron concentration in the F-region irregularities is usually no more than a few per cent greater or less than that in the ambient ionosphere.

The observational and theoretical understanding of these irregularities has proceeded rapidly in recent years, but semiquantitative theories exist only for two or three kinds of Sporadic E.

The charged particles which constitute the ionosphere are formed by ionization of the atoms and molecules of the ambient un-ionized atmosphere. Under geomagnetically quiet conditions, the C region is caused by the ionization of N₂ and O₂ by galactic cosmic rays, but all of the other regions are caused by solar photons in the extreme ultraviolet and x-ray part of the spectrum.

The quiet D region is formed by the ionization of NO—a trace in the atmosphere—by the solar Lyman- α line at 1261Å. The quiet E and F regions are formed by the ionization of all of the atmospheric constituents there, i.e., N₂, O₂, and O (which is formed from O₂ by photodissociation), by solar photons in different bands between about 10 and 1027Å. The heliosphere is formed by the ionization of He by wavelengths between 165 and 504Å. Photoionization of H by wavelengths between 165 and 911Å makes some contribution to the protonosphere, but another process, to be discussed later, is dominant.

The rate of ionization is occasionally considerably increased by several kinds of disturbances. The C and lower D regions in the polar regions are enhanced by ionization by solar protons during Polar Cap Absorption events. Enhancements of the D, E, and F regions by ionization by fast electrons (called Auroral Absorption events) are frequent in the polar regions but occur at lower latitudes only during geomagnetic disturbances. The D, E, and F regions are also

enhanced by solar photons emitted during solar flares; these enhancements are called Sudden Ionospheric Disturbances. Enhancements of ionization in the D region cause increased absorption of radio waves, with deleterious effects on radio communication.

The positive and negative charges eventually recombine to form neutral particles. However, some of the species of ions—especially the atomic ions—are more likely to undergo reactions which form other species of ions than they are to recombine with electrons. Thus, the protons in the protonosphere are lost by transferring their charge to O atoms to form O⁺ ions. Since the ionization potentials of H and O are almost equal, this reaction can also proceed in the other direction to form H⁺ from O⁺. This is the principal source of ionization in the protonosphere. The He⁺ in the heliosphere is lost by chemical reactions with N₂ and O₂ which form N⁺ and O⁺. These atomic ions are lost by further chemical reactions with N₂ and O₂ which form NO⁺ and O₂⁺. These molecular ions can then recombine with electrons by a process (dissociative recombination) which is about 10⁵ times faster than the recombination of atomic ions (by radiative recombination). Also, in the C and D regions the electrons can attach themselves to neutral particles to form negative ions, which can then either recombine with positive ions or be detached.

Above about 200 km, that is, in the F2 layer, the heliosphere and the protonosphere, plasma diffusion plays an important role in determining the distribution of ionization. The forces which cause this diffusion are primarily gravity, concentration gradients, and electric fields. Above the peak of the F2 layer, at about 300 km, the ionospheric plasma tends to be in diffusive equilibrium, and the electron concentration decreases exponentially with height, with a logarithmic decrement which is proportional to the mass of the ions.

The complex variations of the electron concentration in the ionospheric regions are the results of the interplay among the processes of ionization, recombination, and diffusion, each of which itself has a complex dependence on time of day, season, latitude, and solar and geomagnetic activity. Although the general nature of these various dependences is known, their rates are not yet known well enough to form a satisfactory quantitative model of the ionosphere.

IRRADIATION, DISPLACED ATOMS

High-energy particles interact with the atoms of a solid in several ways and thereby produce disturbances in the atomic and electronic structure of the solid. The practical importance of such interactions is that many physical properties are very sensitive to the disturbances produced by radiation. Drastic changes, often deleterious and therefore referred to as radiation damage, may occur in such properties of practical importance as dimensional stability, mechanical and electrical properties, thermal conductivity, etc. The scientific importance of the field arises from the fact that the study of radiation effects leads to new and valuable insight into the properties of imperfections in solids. Irradiation with energetic particles has become a powerful tool of solid-state research, since a large number of imperfections can be introduced into a solid in a reasonably well-controlled manner.

The most important basic processes arising from the interaction of high-energy particles with solids may be classified as follows: (1) production of displaced and excited electrons, i.e., ionization; (2) production of displaced atoms by direct collision; and (3) production of fission and thermal spikes. In some cases transmutation effects also have to be taken into account. Attention is focused here on the production and nature of displaced atoms. Neglect of ionization is realistic for metals whose electrical conductivity is high, because in such metals any ionization is so rapidly neutralized that ionization effects are not observable. In insulators, ionization effects are of primary importance, and in semiconductors, both ionization effects and displacement production are important. Ionization effects are discussed under such entries as COLOR CENTERS; RADIATION CHEMISTRY; RADIATION, IONIZING, BASIC INTERACTIONS. Fission and thermal spikes, rather complex disturbances, are important in materials of high atomic number irradiated with massive particles but will not be further discussed here (see references 3 and 4).

If a bombarding particle makes an elastic collision with an atom and transfers to it an amount of energy larger than the displacement threshold energy (typically about 25 eV), the atom will be displaced from its lattice position. In most cases the displaced atom, or knock-on, has enough recoil energy to travel a few atomic distances from its initial position, either directly through the lattice or via a series of replacement collisions (see below), before coming to rest in an interstitial position. Thus, the fundamental displacement pair is produced: the displaced atom or interstitial, and the lattice site which was left empty, the vacancy. A complete theory of defect production at all energies is not yet at hand, but a great deal of insight can be obtained from theoretical dynamic studies at rather low energies made with high-speed computers. In Fig. 1 three important processes that occur during displacement production are illustrated. Atom A, the primary knock-on, is assumed to have been struck

by a bombarding particle and to have been given an initial energy of 40 eV in the direction indicated by the arrow at A. The lines in this Figure are the paths followed by the individual particles. By subsequent collisions, an interstitial has been produced at location D and a vacancy left behind at position A. Replacement collisions have occurred at locations B and C, where atom A replaced atom B and, in turn, atom B replaced atom C. Focusing collisions, preferential propagation of energy along rows of close-packed atoms, are also clearly seen in the figure. At higher energies the focusing collisions transport matter as well as energy and thus create interstitial atoms, after a series of replacement collisions, at some distance from the original point of impact. The picture becomes considerably more complex at still higher energies. Thus, results of experiments involving irradiations with electrons or gamma rays in the few-MeV range are much easier to interpret than the more complex damage resulting from irradiation with neutrons (in a reactor) or with heavy charged particles.

The displacement process is clearly quite complex, and no complete quantitative theory has been formulated. The average number of displaced atoms can be estimated by means of a simple model based on binary collisions. Comparison with experiment shows rather good agreement in the case of metals irradiated with electrons. Upon heavy particle or reactor irradiation, the experimentally observed concentration of displaced atoms is less than that predicted by theory by a factor of 5 to 10. A rather crude, but convenient, number to remember is that in most metals one atomic per cent vacancy-interstitial pairs are produced by 10^{20} neutrons/cm² in a reactor exposure to fast (epithermal) neutrons.

A convenient and accurate measure of defect concentration is the low-temperature electrical resistivity, or residual resistivity, of a metal. Much of the fundamental information available has been obtained by this technique. Other physical property changes, however, are far more important from a practical standpoint. For example, metals generally harden considerably upon reactor irradiation. The increase in critical shear stress is usually accompanied by a reduction in ductility leading to increased brittleness. Such changes are intricate since they involve the interaction of the radiation-induced defects with static and moving dislocations, and a full interpretation of the experiments is not at hand. As another example, graphite exhibits a large increase in volume upon reactor irradiation. It is quite clear in this case that the radiation-induced interstitials lodge between the graphite planes and push these planes apart.

A very important fundamental and practical property of the radiation-induced defects is their mobility. The defects can migrate in the solid from one position to another by surmounting an energy barrier, i.e., their migration is characterized by an activation energy. Since an irradiated crystal is not in thermodynamic equilibrium, it will tend to revert to its stable unirradiated form

Fig. 1. Atomic paths, calculated dynamically, produced by a 40-eV knock-on in copper. The primary knock-on collision was at lattice position A (from reference 6).

at temperatures high enough for the defects to be mobile, i.e., the crystal can be annealed. The kinetics of the annealing process can be quite complex, since usually several competing processes are going on such as vacancy-interstitial annihilation, defect migration to external and internal surfaces, defect aggregation, etc. From the fundamental standpoint, a great deal can be learned about the characteristics of the defects from detailed annealing experiments. The practical importance of annealing is that by raising the temperature undesirable radiation damage can be minimized. The situation is more complicated in alloys, since the migration of defects is equivalent to diffusion, which may result in metallurgical changes. Indeed, radiation-enhanced diffusion, nucleation, precipitation, and phase transformation have been observed.

Ionic crystals are discussed elsewhere. In semiconductors, the fundamental displacement process is very similar to the one already described. However, the radiation-induced defects in semiconductors have localized energy states associated

with them which alter the concentration and mobility of charge carriers and thereby lead to drastic and important changes in the electronic properties. Some of the defect energy states are occupied by electrons and are therefore donors, while others are vacant and act as acceptors. In some semiconducting crystals, the radiation-induced changes go very far indeed. For example, germanium and gallium antimonide are converted from *n*-type to *p*-type upon irradiation. The sensitivity of semiconductor devices to radiation is of great practical importance in many space applications (solar cells, electronic control and detection devices, etc.).

ISOTOPES

The word "isotopes," stemming from the Greek words, *isos* (same) and *topos* (place), refers to atoms of an element which have differing masses. The term was first proposed by Soddy in 1913 to designate substances having different atomic weights and yet having chemical properties which were so closely allied that no chemical method was effective in producing a separation. Hence, Soddy suggested that they were chemically identical; i.e., they occupied the same place in the periodic table. In 1905, Boldwood noted the presence of lead in uranium minerals and suggested that this might be the end product of the uranium series. As a result of the study of the relation of lead to uranium in a large number of minerals, this view was generally adopted. Soddy concluded that the end products of the uranium and thorium series should be lead with isotopic weights of 206 and 208, respectively, whereas ordinary lead has an atomic weight of 207.2. Soddy and Hyman reported in 1914 that the atomic weight of lead as found in thorite (consisting mainly of thorium, 1 to 2 per cent uranium, and 0.4 per cent lead) indeed had a slightly greater atomic weight than that of ordinary lead.

Some elements such as sodium and cobalt are mononuclidic; i.e., all of the natural stable atoms have the same mass. Others have many natural stable isotopes, as for example, tin, which is made up of atoms of ten different masses as it occurs in nature. Since the atoms in multinuclidic elements are chemically identical and have the same number of protons in the nucleus, the varying masses are accounted for by the variable number of neutrons in the nucleus.

Isotopes are divided into two groups: stable and radioactive (unstable). The total known isotopes number about 1500, of which 280 are stable and the balance are radioactive, having a transient existence ranging from millionths of a second to millions of years. Radioisotopes undergo transformation, or decay, emitting alpha, beta, gamma, or x-radiations during their return to a stable condition (see RADIOACTIVITY).

Isotopes, both stable and radioactive, have grown in importance to science and technology in

the last 40 years. Since atoms can be marked by their radioactivity, or in some cases by an atypical isotopic composition, the elements can be traced, a procedure of great value in physical and biological science, technology, and medical diagnosis. Further, radioisotopes emit corpuscular and/or electromagnetic radiations that can be used to probe into and through matter, affect it chemically and physically, produce heat and light, kill microorganisms, and perform many other tasks of benefit in today's complex industrial society.

Stable Isotopes. By 1900, physicists had found that positively charged particles formed by the passage of an electric discharge through an evacuated tube consisted of molecular ions of the gas present in the tube. Deflection of these positive rays by electric and magnetic fields offered a sensitive tool to study gaseous elements. By allowing the rays from a given element to fall on a photographic plate, a series of parabolic streaks were observed, each corresponding to a definite value of mass-to-charge ratio (m/e). Positive ray photographs of neon (atomic weight 20.2) obtained by Thomson exhibited, among other things, a heavy neon line and a faint line at 22. In an effort to elucidate the situation, Thomson's assistant, Aston, passed neon gas through a porous pipe-clay tube repeatedly and was able to show a significant alteration in the atomic weight of the two extreme fractions. This alteration was reflected in changes in the relative brightness of the two lines in subsequent positive ray analyses.

Aston proceeded to redesign the positive ray apparatus so that the particles having the same mass were brought to a focus to produce a sharp line rather than a parabola; the resulting instrument was called a mass spectrograph. With this instrument, Aston was able to confirm the finding that neon exists in at least two forms (atomic weights of 20 and 22) and that the proportions appeared to be 10:1, giving an average atomic weight of 20.2 to neon. Aston next analyzed chlorine and also found that this gave two lines, corresponding to 35 and 37.

The pioneering work of Aston and Dempster in 1918-19 with the electromagnetic mass spectrometer is the historical starting point for separation and study of the isotopes of the elements. The electromagnetic separation of isotopes is relatively simple in principle (see MASS SPECTROMETRY).

Production of Stable Isotopes. There are a number of possible ways of separating isotopes using electromagnetic principles. However, the large-scale mass spectrometer known as a *calutron* is the device now used almost exclusively. Within a tank maintained at high vacuum, ions of an element are produced by vaporization at high temperature, sometimes assisted by a chemical agent such as carbon tetrachloride (chlorination). The ions are accelerated by an electric potential and projected as a beam across a magnetic field. While the electromagnetic forces acting to curve the path of the ions are essentially the same on each of the ions, they curve into different paths because the masses of the several isotopes are

different. After traversing a circular path of 180 to 300 , the divergent particle paths are interrupted by catcher pockets, usually made of slots in graphite or copper, water-cooled "receivers." The isotopes are then chemically recovered from the receiver pockets.

Very small amounts of material can be separated in the calutron, since it separates the isotopes literally atom-by-atom. Nevertheless, ion currents up to one ampere can be maintained, allowing kilograms of material to be separated in a machine operating over a year's time. Virtually all of the isotopes of the elements have been separated in relatively high purity at Oak Ridge National Laboratory. The details on separated isotopes

available and the procedures to be used in obtaining them are given in the ORNL Isotopes Catalog.

A number of gaseous elements, such as krypton, neon, and argon, are separated by thermal diffusion. Chemical exchange is used with such isotopes as hydrogen and nitrogen. Huge gaseous diffusion plants are used to enrich large quantities of ^{235}U . The electrolytic method is used for deuterium separation, and distillation has been used for the enrichment of mercury isotopes. More recently large high-speed centrifuges are being investigated for large-scale isotopic separations. Other than the well-known uses of ^{235}U and ^3H in large-scale nuclear work, the separated isotopes have been used primarily for fundamental scientific work, such as measurement of nuclear cross sections, but there is a growing utilization of isotopic materials in all fields of fundamental research and as target materials for radioisotope production.

Radioisotopes. Some radioisotopes occur in nature, e.g., uranium, radium, and thorium—ordinarily accompanied by their radioactive daughters (decay products). Radioisotopes that occur in nature have half-lives greater than about 10^8 years or are the decay products of parent radioisotopes of such long-lived radioisotopes. These primordial radioisotopes were produced when the earth was formed and have not yet decayed away in the ensuing several billion years. Some shorter-lived radio-isotopes such as 5570-year ^{14}C and 12.46-year ^3H are formed by cosmic ray inter-actions with atmospheric nitrogen and hydrogen. Irene Curie observed and identified the first artificially induced radioactivity in 1934 by irradiating targets of aluminium, magnesium, and boron with alpha particles and noting that the targets continued to emit radiation after the α -source was removed. This discovery offered the first chemical proof of artificial transmutation. After the introduction of the cyclotron and other particle accelerators, many elements were bombarded with deuterons and protons to produce hundreds of new radioisotopes, including the well-known ^{131}I , ^{32}P , and ^{14}C . Large-scale production of radioisotopes, however, did not come about until nuclear reactors were available after World War II to supply enormous amounts of neutrons. Of the naturally occurring isotopes of the elements, roughly 280 are stable, and about 25 may be considered naturally radioactive. The number of artificially produced isotopes reached 200 in 1937, and with the nuclear reactor as a source of neutrons in World War II, about 450⁺ artificially radioactive isotopes were identified by 1944, and over 1500 by 1964. Each element has at least one radioactive isotope, and some have as many as 30.

Production of Radioisotopes. Radioisotopes are produced by disturbing a preferred neutron-proton ratio in the nuclei of elements. This is done by adding or removing neutrons, by adding or removing charged particles such as protons, or by a combination of both. Usually, a nuclear reactor is used as the source of neutrons; a cyclotron or other particle accelerator is used as the

source of charged particles. The radionuclides formed by increasing the neutron-proton ratio generally decay (or transform) back to a stable condition by having a neutron transform to a proton, with the emission of a negative electron (beta particle, ${}_{-1}^0\beta$) and a neutrino (ν)—an almost undetectable uncharged particle of negligible mass. (see NUCLEAR REACTIONS).

For those radionuclides resulting from an increase in the proton-neutron ratio, the transformation again tends to reverse the cause for instability, and a proton in the nucleus is transformed into a neutron, with the emission of a positive beta particle (positron, ${}_{+1}^0\beta$).

In some cases, nuclei which are unstable because of an excess of protons (called neutron-deficient nuclei) will regain stability by capturing an orbital electron, ${}_{-1}^0e$:

Characteristic x-rays of the product element are emitted during the refilling of the orbital electron shells.

In the transformation processes described above, gamma (γ) radiation may or may not be emitted; these photons may undergo internal conversion whereby the transition between the two energy stages of a nucleus is not evidenced by the emission of a photon. Instead, the energy is imparted to an orbital electron, which is ejected from the atom.

For some nuclei, only gamma radiation is emitted for the de-excitation from a metastable or isomeric state. Such decay is termed isomeric transition (IT) and is characterized by no change in mass number or atomic number.

Many radioactive nuclides decay by two or more modes, so that ${}_{-1}^0\beta$, ${}_{+1}^0\beta$, γ , ${}_{-1}^0e$ transformations with associated emission and x-radiation are not uncommon. The *branching ratio* defines the relative amounts of each mode of decay.

For heavy nuclei ($Z \geq 82$), the transformation to a more stable configuration usually takes place by the emission of an alpha particle (α or ${}^4_2\text{He}$), sometimes accompanied by gamma emission.

The bulk of the artificially produced radioisotopes are made by neutron reactions in the high-volume neutron fluxes available in NUCLEAR REACTORS. Neutrons, having no charge, can easily penetrate the coulombic barriers of the nucleus. The atomic nuclei of the elements vary in their ability to capture thermal neutrons (i.e., neutrons slowed down to ~ 0.04 eV) according to their *cross sections*, a value which expresses the probability of capture of a neutron of a certain speed as it passes near a nucleus (see CROSS SECTIONS AND STOPPING POWER). When target materials are placed in the reactor and subjected to a flux of neutrons (amount of neutrons traversing a unit

area per unit time), neutrons are captured in proportion to cross sections of the target element atoms present. Certain materials, such as aluminum and graphite, have such low neutron capture cross sections that few neutrons are captured; others, such as cadmium, have such high cross sections that a thin foil will absorb almost all the thermal neutrons impinging upon it.

Radioisotopes are produced in a nuclear reactor by several different processes. Those processes that produce appreciable quantities of radioisotopes are described below.

(1) (n, γ) Process. In the (n, γ) process, which is most common, a neutron is captured by a target atom, and a gamma photon is emitted immediately. Since no change of the atomic number (charge on the nucleus) occurs, the element remains the same as the target material. The radioelement cannot be separated chemically unless a recoil collection is made, as in the Szilard-Chalmers process. The (n, γ) reaction is primarily a thermal-neutron (low-energy) reaction.

For example:

A radioisotope produced by this method sometimes decays by beta emission to a radioactive daughter with a different atomic number. The daughter can be separated chemically to obtain high specific activity* material. For example:

(2) (n, p) Process. In the (n, p) process, which requires neutrons of higher-than-thermal energies†, a neutron enters a target nucleus with sufficient energy to cause a proton to be released. The atomic number is reduced by 1, and the affected atom is transmuted into a different element, which can be separated chemically from the target material. Through the chemical separation, high-specific activity material can be obtained. For Example:

(3) (n, α) Process. The (n, α) process, like the (n, p) process, requires high-energy neutrons. In the (n, α) process, a neutron of high energy enters a target atom and causes an alpha particle to be emitted. The atomic number of the target atom is reduced by 2, and a chemical separation is possible. By means of chemical separation,

* *Specific activity* is the amount of radioisotope per unit weight of the total element and is usually expressed as curies or millicuries/gram.

† A few exceptions are found among reactions with the light nuclei in cases where the binding energy of a proton or particle is appreciably lower than that of a neutron: the reactions ${}^{10}\text{B}(n, p){}^{10}\text{Be}$, ${}^{14}\text{N}(n, p){}^{14}\text{C}$, ${}^{35}\text{Cl}(n, p){}^{35}\text{S}$, ${}^{10}\text{B}(n, \alpha){}^7\text{Li}$, and ${}^6\text{Li}(n, \alpha){}^3\text{H}$ occur with thermal neutrons.

high-specific-activity material can be obtained. For example:

(4) Fission. In the fission process, most of the fragments of uranium atoms which have undergone fission are radioactive atoms ranging from atomic number 30 through atomic number 64. They can be concentrated chemically for high specific activities, but since several isotopes of any one element are often produced, the isotopic purity will not necessarily be as high as that of radioisotopes produced by (n, p) and (n, α) reactions. The isotopic purity will depend somewhat upon the length of time that the uranium was exposed to neutrons and upon the elapsed time between removal from the reactor and the chemical separation.

The basic equation for radioisotope production is

$$A \xrightarrow{\sigma_A} B \xrightarrow[\sigma_B]{\lambda_B}$$

The target atom (A) captures neutrons to produce the product nuclide (B), which in turn is transformed by decay or further neutron capture. The effective cross sections (σ_A , σ_B) and the decay rate constant (λ_B) enable the rate and equilibrium values for the transformation to be calculated for any particular irradiation conditions. The exact solution for the differential equation describing these rate processes for the number of atoms (N) of product formed at time (t) in neutron flux ϕ is,

$$\lambda_B N_B = \frac{\lambda_B \phi \sigma_A N_A}{\lambda_B + \phi(\sigma_B - \sigma_A)} [e^{-\phi \sigma_A t} - e^{-(\phi \sigma_B + \lambda_B)t}]$$

In most cases, one can neglect the "burn-up" of the target atoms and the product radioisotope. In such cases, the above equation then reduces to:

$$\lambda_B N_B = N_{A0} \phi \sigma_A (1 - e^{-\lambda_B t})$$

Here N_{A0} refers to the number of original target atoms at time zero.

For irradiations of sufficient length ($t \gg T_{1/2}$), and again neglecting burn-up, the saturation factor ($1 - e^{-\lambda_B t}$) approaches 1 and the equation further reduces to

$$\lambda_B N_B = N_{A0} \phi \sigma_A$$

Isotope Processing. The techniques used for the processing of ultrahigh purity chemicals are required for isotope work in recovering stable isotopes, preparing target materials, and separating and purifying radioisotopes. Practically every technique from traditional wet chemistry to ion exchange and chromatography are utilized, often with high-purity radioisotopes, at very low concentration levels (e.g., micro-grams per liter). Sophisticated analytical methods (e.g., mass and radiation spectral analysis) are also required and make up a significant portion of the cost of isotope preparations.

KEPLER'S LAWS OF PLANETARY MOTION

The German astronomer and mathematician, Johannes Kepler (1571–1630), worked in the late 1500's with the Danish astronomer, Tycho Brahe, one of the most careful observers of astronomical motions of the pre-telescopic centuries. When Tycho Brahe died in 1601, Kepler inherited his data books to which he devoted several years of intensive work in an effort to bring orderly relations to light. Kepler was successful in deriving three experimental laws of planetary motion that led the way to the presently understood dynamics of the solar system. The first two laws were published in Prague in 1609, about the time when Galileo was first using his telescope to make significant discoveries about the planets and their moons; the third law did not appear until 1619.

Stated briefly, these laws are (see Fig. 1).

- (1) Each planet moves in an elliptical orbit with the sun at one focus of the ellipse.
- (2) The line from sun to any planet sweeps out equal areas of space in equal lengths of time.
- (3) The squares of the sidereal periods of the several planets are proportional to the cubes of their mean distances from the sun.

FIG. 1. Elliptic orbit of planet with Sun at one focus. Areas A and P are described in equal length of time.

An explanation of each of these laws follows, but first they should be seen against the background of the cosmology of Kepler's time, as they signify a distinct break with ancient cosmology and they were a marked extension of Copernican ideas. Until Kepler's time, it had been supposed

that the planets moved in circular orbits, that being the most perfect of curves and hence the path of the "perfect" celestial matter of which they were presumably composed. As observational accuracy increased, it became necessary to develop complex orbit by epicycles to preserve this idea of circular motion. The spectroscope would not show until after 1860 that heavenly matter and earthly matter were both composed of the same chemical elements. It is greatly to Kepler's credit that he established these three laws on such precise data and with such care, even though he himself did not know what they meant. In the ten years intervening between announcing laws (1) and (2) and publishing law (3), Kepler made innumerable attempts to find a relation between periods and distances in the solar system: some of these bordered on pure numerology and mysticism. Kepler had no adequate notion of force and hence he was prevented from continuing with his laws to their consequences, as Sir Isaac Newton did some five or six decades later.

Newton employed Kepler's laws to the full. The fact that planets move in ellipses with the sun at one focus he showed to be possible only if a force prevailed between sun and planet exactly proportional to the inverse square of the distance between them. This gave him confidence in the "inverse square law" (see GRAVITATION). The second law, Newton showed, was evidence of the great principle of conservation of angular momentum which Newton himself did so much to establish. Any object moving under a "central force," or a force directed toward a fixed point, will qualify for Kepler's second law, namely of sweeping out equal areas in equal times. However, although this law is not limited to inverse square forces, it shows, when coupled with the first law, that a planet such as the earth will move more rapidly about the sun at perihelion (closest to sun) than at aphelion (farthest from sun), as is observed. Finally, the third law falls into line as a necessary consequence if an inverse square law of force holds. One by-product of this law is the fact that the same force field is present from the primary body for each of the planets, diminishing with distance, but indicating that the force depends upon the *product* of the masses of sun and planet.

It is interesting to see how easily the third law of Kepler's may be "discovered" by the use of

FIG. 2. Graph on log-log paper of relative mean distances of planets from sun, in Astronomical Units (where sun-earth distance is 1 A.U.), vs. period of planets about the sun in years. Straight-line graph with slope $3/2$ means constant ratio of R^3 to T^2 , which Kepler found in 1619. Planets beyond Saturn, unknown to Kepler, can be added.

techniques not available to Kepler. Kepler knew from Tycho's observations the *relative* distances from sun to any of the planets (out as far as Saturn); such relative distances can be found without knowing actual distances which were not found for another century. If one plots these relative distances against the planetary periods, using log-log graph paper, there results a fine straight line graph of points, one point for each planet, for which the slope is $3/2$ (Fig. 2). This shows at once that there is a constant ratio of R^3/T^2 ; or the ratio of the cube of R , mean distance from the sun, to the square of the sidereal period T , is the same ratio for all planets. Thus, in a few minutes, one may discover what it took Kepler ten years to find!

It was probably fortunate that Kepler made his most intensive study on the orbit of the planet Mars, inasmuch as that planet has the greatest eccentricity of orbit of any of the planets known in his time. Thus he could cast out circular orbits in favor of ellipses. (Only Pluto, discovered 300 years later has greater eccentricity.) One may, by relatively simple garden observation (non-telescopic), discover the eccentricity of the earth's own orbit by introducing a useful point of view. Ordinarily, astronomers talk about the place of the sun among the stars in its annual apparent pilgrimage along the ecliptic, or the plane of the

earth's orbit. However, it is not possible to see the stars when the sun is among them in the daytime, and it is therefore meaningful to ask "Where is the earth among the stars as seen from the sun?" This reversal of the point of view then means "What star (or position among the stars) is on the local meridian at true midnight, when the sun is on the anti-meridian beneath the observer's feet?" A vector drawn from sun to earth and thence to the stars would then be found to move eastward among the stars just as the earth proceeds eastward day by day around the sun. However, the rate of advance of this vector is not constant, although its *average* rate is only slightly less than one degree per day. Consequently, one would observe, by taking into account the equation of time (which reflects the variable apparent motion of the sun among the stars), that this "midnight vector" (see Fig. 3) does not progress uniformly: its rate of eastward motion is greatest near January 1 when it projects into the midst of the winter stars between Betelgeuse and Procyon; and it progresses least rapidly around July 1 when it projects into the region of the sky between Vega and Altair.

According to Kepler's second law, the product of angular velocity of the earth and the *square* of its radius vector from the sun should be constant, which means that in January when the earth is

FIG. 3. The "place of the earth among the stars" is given by vector from sun to earth to celestial sphere (at midnight); the eastward sweep of this vector varies as R (the distance between sun and earth) varies, according to Kepler's second law; the angular speed of the vector multiplied by R^2 is constant.

nearest to the sun, its angular velocity as measured by this technique, should be greater by about 7 per cent than in July when the earth is some 3 per cent farther from the sun. Despite the fact that star days are all the same length, from the meridian crossing of any given star until its return to the meridian, the rate of progress of the true midnight meridian through the stars is not constant, but variable. It requires careful observation to measure the ratio of perihelion to aphelion distances in the manner suggested, but it can be done.

More simply, one may observe the application of Kepler's laws to the motion of the moon, for in one month one may discover that at certain times of the month when the moon is near perigee, or nearest the earth, it advances eastward among the stars at a greater rate than it advances about 13.5 days later when it is at apogee. Likewise, if one has any means for observing the apparent diameter of the moon from one end of its crescent to the other, one can also find that at perigee it subtends a greater angle by 11 per cent than at apogee. The variation in angular speed is quite pronounced inasmuch as the ratio of maximum to minimum distance is about 252/228 (in thousand miles) or 1.11. Conservation of momentum says that the product of angular speed and the *square* of the radius vector is constant, consistent with the constancy of areal velocity which depends on the square of the radius vector. Hence, the maximum angular speed divided by the minimum angular speed would be $(1.11)^2$ or about 1.24. The maximum speed exceeds the minimum by some 24 per cent, a quantity rather easily observed if one takes a little care and patience.

Kepler's laws are, of course, applicable to the motion of artificial or man-launched satellites

FIG. 4. Satellites of the earth - log log graph of mean distance from center of earth vs period of satellite, from Sputnik I (1957) to moon. This Figure is similar to Fig. 2 except that the earth rather than the sun controls the satellite periods. Again, the R^3/T^2 constant ratio shows up in the $3/2$ slope of the straight-line graph. Several representative satellites are listed.

circling the earth. One may draw a graph similar to that drawn for the planets, except that now the earth rather than the sun is the controlling body. Just as no satellite could possibly continue to orbit the sun if its mean distance were less than the radius of the sun, no satellite can continue to orbit the earth if its orbit intersects the earth. (In fact, close-by satellites are captured by the atmosphere and such satellites are likely to be burned up in the upper atmosphere as their kinetic energy is rapidly turned into heat.) It is interesting, however, to draw a straight line on our log-log graph from the point representing Sputnik I, the first artificial satellite launched in 1957 with its period of 96 minutes, to the moon with its period of 27.32 days. It will be found that other satellites lie as points on this line. The semi-major axis (or mean distance) of each satellite's orbit may be found from the addition of the earth's diameter to the usually published perigee and apogee distances, most commonly offered as minimum and maximum distances of the satellite above the earth's surface. Thus, for a satellite with minimum distance 1730 miles and maximum 2120 miles from earth's surface, we add 7950 miles (for the earth's diameter) to the sum of these figures and divide by 2 to obtain 5900 miles as the mean distance of the satellite from the center of the earth, the point toward which the gravitational forces are effectively directed. Armed with this 5900-mile mean distance, we may read the period of the satellite directly from the graph,

FIG. 5. Kepler's law of areas holds also for "central force" of repulsion between alpha particle and atomic nucleus; path of alpha particle is a hyperbola with nucleus in far focus. Areas 1, 2, 3, 4, 5, 6, etc., are equal and are described in equal lengths of time. A high-speed comet injected from outer space might, under gravity, describe the same kind of path, but with the sun at the near focus F.

namely about 153 minutes (2.55 hours). (This happens to correspond with USAF satellite 1962 K 1, launched on April 9, 1962 at such elevation that it is likely to continue to orbit for many years.)

It may be remarked in conclusion that Kepler's law of areas is applicable also to repulsive forces. The path of an atomic particle, such as a proton, in the field of an atomic nucleus is a hyperbola because of the strong repulsion between the two. In this case, the repulsive center is situated at the far focus of the hyperbola (see Fig. 5). Rutherford made full use of this idea in his brilliant discovery of the atomic nucleus (1911).

KERR EFFECTS

The Kerr effect is the occurrence of double refraction in a substance, when it is placed in an electric field. A more exact name is the *Kerr electro-optic* effect. It was first discovered for glass, in 1875, but it exists for liquids and gases also.

An ordinary dielectric medium has a single value for the index of refraction at any given wavelength of electromagnetic radiation, independent of polarization or direction of propagation of the radiation. In a uniaxial crystalline substance, there are two indices of refraction: the ordinary index which refers to radiation polarized with its electric vector perpendicular to the optic axis (a direction in the crystal), and the extraordinary index which refers to radiation with its electric vector parallel to the optic axis.

A substance which exhibits the Kerr effect is ordinarily singly refracting, but it becomes doubly refracting when an external electric field is applied. The substance behaves like a uniaxial crystal, with the optic axis parallel to the electric field. Liquids generally show larger effects than either solids or gases.

The difference in indices of refraction is proportional to the square of the applied electric field strength, and hence the Kerr effect is sometimes called the quadratic electro-optic effect. The expression for the optical path difference is given by

$$\Delta = (n_E - n_O)l = KE^2l/\lambda$$

where

- n_E extraordinary index
- n_O ordinary index
- l path length in the medium
- E electric field strength
- λ wavelength in vacuum
- K Kerr constant.

The constant is usually positive, decreasing with an increase in wavelength and with an increase in temperature. The effect is caused by either natural or induced optical anisotropy of the

individual molecules of the medium, and a lining up of the molecules by the applied electric field. The effect is particularly large for liquids made up of polar molecules with large anisotropies. Nitrobenzene, for example, gives an optical path difference of approximately $1/40$ wavelength in the visible region of the spectrum, for a field strength of 10000 volts/cm and a 1-cm path length. The Kerr effect can be very useful in helping to determine the structure of complex molecules.

Recent discoveries have shown the existence of an enormous quadratic electro-optic effect in certain crystals, notably perovskites in the paraelectric phase. The effect can be several thousand times larger than that observed for nitrobenzene and is independent of temperature. The theoretical explanation requires knowledge about both electronic and ionic states of the crystalline lattice constituents.

Kerr cells are light shutters constructed from substances showing large Kerr effects. One type of widely used cell contains nitrobenzene placed between capacitor plates or electrodes. The cell itself is situated between a crossed polarizer and analyzer combination. In the absence of an electric field, no light is transmitted. When the electric field is applied, its strength is chosen so that the cell becomes a half-wave plate (the optical path difference is one-half wavelength). The plane of polarization of the light is therefore rotated by 90° , and the light is transmitted. An important property of the cell is its extinction ratio, or ratio of the light transmitted when the cell is closed to that transmitted when it is open. A cell filled with extremely pure nitrobenzene can give a ratio as low as 10^{-5} to 1. Cells of the perovskites are closer to 10^{-2} to 1. Another important property of the Kerr cell is the frequency with which it can be turned on and off. Frequencies as high as 10^{10} /sec are attainable in some instances. The inductance and capacitance of the cell, as well as relaxation effects in the medium, must be given considerable attention in the design of a cell. Also, the transit time of the light across the cell must be much less than the period of the applied field, in order for the cell to be effective.

A second effect is known as the *Kerr Magneto-optic* effect. It is the change in polarization of light reflected from a polished metal pole of a magnet. Linearly polarized light incident normally, is reflected as elliptically polarized light. This effect has not as yet proved useful in a practical device, nor for determination of fundamental properties of substances, and therefore has not been investigated as thoroughly as the electro-optic effect.

KINETIC THEORY

The kinetic theory is a branch of THEORETICAL PHYSICS developed in the nineteenth century to explain and calculate the properties of fluids. It is most useful for studying the physical properties of gases, but it can also be applied to liquids, electrons in metals, and neutrons passing through solids. The word "kinetic" means "pertaining to motion," in this case the motion of molecules or subatomic particles.

Historical Development. The first attempt to develop a kinetic theory of gases was made in 1738 by the Swiss mathematician Daniel Bernoulli. Bernoulli began with the idea that matter consists of tiny atoms moving about rapidly in all directions, which the Greek philosopher Democritus had presented, but was unable to prove. Bernoulli showed that the collisions of atoms against the walls of a container would produce a pressure which would be inversely proportional to the total volume of the container; he assumed that the space occupied by the atoms themselves is negligible compared to the total volume of the container and that the rest of the space is empty. He also found that the pressure would be directly proportional to the kinetic energy of motion of the atoms if the velocities of the atoms are changed while the volume is kept fixed. (The kinetic energy of an atom is half its mass multiplied by the square of its velocity.)

The British scientist Robert Boyle had already shown in 1662 that the pressure of air varies inversely as its volume if the temperature is held constant (see GAS LAWS). Thus Bernoulli's theory was able to explain a well-known fundamental property of air and other gases. It was also known that the pressure of a gas confined in a fixed volume increases with temperature. However, it was not until about 1800 that there was enough experimental evidence, and an accurate enough temperature scale, for Gay-Lussac (French) and others to establish a quantitative relation between pressure and temperature. This relation can be expressed by saying that pressure is proportional to the temperature measured from "absolute zero" (though it was not until later in the nineteenth century that the idea of absolute zero temperature was generally accepted). According to the kinetic theory, the absolute temperature is proportional to the kinetic energy of motion of molecules in a gas.

The kinetic theory was proposed again in the first half of the nineteenth century by two British

scientists, John Herapath and J. J. Waterston. Neither of them was familiar with Bernoulli's theory, which had not made much impression on the world of science. Waterston obtained one important new result, which is now known as the "equipartition theorem": in a mixture of two or more different gases at the same temperature, the average kinetic energy of each kind of molecule will be the same. This means that heavy molecules will tend to move more slowly than light molecules, since when the mass of a molecule is greater, its velocity must be less in order to keep the kinetic energy the same.

In 1859, the German physicist Rudolf Clausius showed how the kinetic theory could be used to explain the rate of mixing of two gases and the rate of heat conduction. His work was extended by James Clerk Maxwell (British), who calculated the viscosity coefficient by the kinetic theory. He found that theoretically the viscosity of a gas should be the same at different pressures, and should increase with temperature. This seemed to go against common sense, but later experiments by Maxwell himself and other physicists showed that the theory is correct. Soon afterward several scientists, starting with Josef Loschmidt (Austrian) in 1865, used the kinetic theory to calculate the diameter of an atom. At this time it began to appear that the atom is something that really exists in nature, since it can be measured, weighed, and counted, and is not merely a philosophical speculation. By then the atomic theory had already been accepted in chemistry as a basis for explaining chemical reactions, but it was the kinetic theory of gases that established the place of atoms in physics.

Starting from the foundations laid by Clausius and Maxwell, Ludwig Boltzman (Austrian) and J. Willard Gibbs (American) worked out systematic methods for calculating all the properties of gases from kinetic theory (see STATISTICAL MECHANICS). Sydney Chapman (British) and David Enskog (Swedish) completed the theory, insofar as it pertains to the transport properties (diffusion, viscosity, and heat conduction) of gases at ordinary densities, although there are still some unsolved problems in the area of high-density gases and liquids, on the one hand, and rarefied (very low density) gases on the other. In the course of working out this theory, Chapman and Enskog discovered that it should be possible to separate the components of a mixture of a gas by making one side of the container hotter than the other. This effect—known as "thermal diffusion"—was soon afterwards established experimentally by Chapman and Dootson (British), thus confirming the prediction based on kinetic theory. (Thermal diffusion was used as one of the methods of separating isotopes of uranium during the development of the atomic bomb in World War II).

Although the kinetic theory was founded on the principles of classical Newtonian mechanics and led to some incorrect results because those principles are not valid on the molecular level, it is now generally agreed that the kinetic theory

is valid for calculating the statistical properties of large numbers of molecules, provided that the properties of the individual molecules themselves are determined experimentally, or from the quantum theory. It is only when one tries to apply the kinetic theory to matter in extreme conditions (very low temperatures or very high densities) that he must take account of quantum-mechanical modifications of the statistical method itself (see QUANTUM THEORY and STATISTICAL MECHANICS).

Main Features of the Theory. By assuming that the major part of the heat energy of a gas consists of kinetic energy of motion of the molecules, one finds that the average velocity of a molecule is several hundred meters per second under ordinary conditions. However, it is a fact of common observation that gases do not actually move as a whole at such speeds; a gas will eventually spread throughout any container in which it is placed, but it may be several seconds or minutes, for example, before chlorine gas generated at one end of a large laboratory is noticed at the other end. According to the kinetic theory, the reason for the relative slowness of gaseous diffusion, in contrast to the high average velocities of individual molecules, is that a molecule can travel on the average only a very short distance (its "mean free path") before it collides with another molecule and changes its direction of motion. In particular, at atmospheric pressure, if the molecular diameter is assumed to be about 0.0000001 cm (which is approximately true for most molecules), the mean free path would be approximately 0.0001 cm. At the same time, the average distance between neighboring molecules would be somewhat more than 0.000001 cm, so that the fraction of the total volume occupied by the molecules themselves is less than 1 part in 1000. The average molecular velocity in air at 15°C is about 460 m/sec, so that a molecule will have about 4 600 000 collisions per second.

To simplify their calculations, Maxwell and Boltzmann made the following assumptions:

(1) Instead of trying to compute the exact path followed by every molecule, they assumed that, because of the enormous frequency of collisions, the velocities and positions of molecules in a gas are distributed at random over all possible values consistent with the known physical state of the gas. For example, it is assumed that the average total velocity is known, as is the temperature (which fixes the mean square velocity). If variations of temperature and density from one place to another can be ignored, then the molecular velocities can be described by a statistical distribution—the "Maxwell distribution"—which is similar to the normal "bell-shaped curve" or law of errors in statistics.

It should be noted that the effect of a large number of collisions is *not* to make all the velocities equal, but rather to produce a wide range of velocities from zero up to very large values—though the probability of large deviations from the average is quite small. The existence of this

"spread" of molecular velocities has been verified directly by various experiments.

(2) The diameter of a molecule is so small, compared to the average distance between molecules, that simultaneous collisions of three or more molecules may be ignored. The validity of this assumption for low-density gases makes it possible to develop a very accurate theory of gas properties, since these properties can be related to the interactions of molecules taken two at a time, and the mathematical description of such two-particle interactions is relatively simple. The corresponding kinetic theory of dense gases and liquids, on the other hand, involves the solution of difficult many-particle problems, and results can be obtained only with the help of very drastic approximations (see MANY-BODY PROBLEM).

(3) In treating the collision of two molecules, one supposes that there is no correlation between their velocities before the collision. In the elementary kinetic theory, one assumes that each molecule has the average velocity characteristic of the region of the gas in which it has most recently undergone a collision. It thus "forgets" its past history every time it collides with another molecule. This is obviously not strictly true for each individual molecule, but it is a useful approximation for dealing with average properties of large numbers of molecules.

In modern physics research, it is usual to distinguish between "equilibrium theory" and "transport theory," both of which grew out of the elementary kinetic theory. Equilibrium theory is described in the article on STATISTICAL MECHANICS (see also EQUILIBRIUM); it is used to study such properties as the heat capacity (amount of heat needed to raise the temperature by a certain amount) and the compressibility (change in volume produced by a small change in pressure). Equilibrium theory also tries to explain the existence of phase transitions, such as the condensation of gases to liquids, or the appearance of magnetic ordering in solids. From the theoretical viewpoint, the calculation of equilibrium properties is simpler than that of transport properties such as viscosity, because one merely averages over all the possible states of the system (i.e., over all possible combinations of velocities and positions of the molecules) without having to worry about how one state follows another in time. TRANSPORT THEORY involves a detailed analysis of molecular collisions in order to determine how changes in the state of the system are related to external forces or nonuniform conditions imposed on it.

One of the most fruitful techniques in transport theory is the use of "Boltzman's equation." This equation describes how the velocity distribution changes as a result of external forces and collisions between molecules. Unfortunately the equation is rather difficult to solve, because the term that expresses the effect of collisions on the velocity distribution is an integral over the values of the (unknown) velocity distribution itself for two colliding molecules. In order to

calculate the transport properties it is necessary to resort to tedious computations with infinite series, except for certain artificial force laws (such as repulsive forces inversely proportional to the fifth power of the distance between two molecules) for which the integral can be simplified. In most cases, the results (as worked out by Chapman and Enskog) do not differ greatly from the ones obtained from the approximate elementary theory. However, the important phenomenon of thermal diffusion was discovered only because of a theoretical prediction by Enskog and Chapman; since the existence of this effect had not even been suggested by the earlier theories, this discovery must be regarded as one of the triumphs of mathematical analysis.

Irreversibility. As indicated above, the kinetic theory assumes that the velocity of a molecule may depend on the conditions in the region where it has just suffered a collision, but is otherwise random—in other words, independent of its previous history. This assumption permits one to use the methods of probability theory even though, in classical mechanics, the actual motions of the molecules are regarded as completely determined by their initial configurations. As long as one uses the theory only to calculate properties of a gas that can actually be measured during a relatively short time, the assumption of randomness leads to no serious errors. However, it introduces an element of irreversibility which is inconsistent with the reversibility of the laws of classical mechanics. (A reversible process is one that can go equally well forwards or backwards, in contrast to an irreversible process, like scrambling an egg, which cannot be undone without a great expenditure of energy.) The irreversible aspect of the kinetic theory is shown most clearly by Boltzmann's "*H*-theorem," which has led to a considerable amount of controversy about the foundations of kinetic theory. Boltzmann showed in 1872 that a certain quantity, later called *H*, which depends on the velocity distribution, must always decrease with time, unless the velocity distribution is Maxwell's distribution, in which case *H* remains constant. In the latter case, which corresponds to the equilibrium state, *H* is proportional to the negative of the entropy (see article on THERMODYNAMICS). Thus the *H*-theorem provides a molecular interpretation of the second law of thermodynamics or, in particular, the principle that the entropy of an isolated system must always increase or remain constant. Irreversible processes are those in which entropy increases. The entropy itself can be regarded as a measure of the degree of randomness or disorder of the gas, although it must be recognized that disorder really means just our own lack of knowledge about the details of molecular configurations. The equilibrium state represents the maximum possible disorder; the *H*-theorem implies that a gas which is initially in a nonequilibrium (partly ordered) state will eventually reach equilibrium and then stay there forever if it is not disturbed.

If the long-term consequences of the *H*-theorem

were applicable to all matter in the universe, one might expect that the universe would eventually "run down"; although the total energy might always remain the same, no useful work could be done with this energy because all matter would be at the same temperature (see THERMODYNAMICS). This final state has been called the "heat death" of the universe.

The contradiction between the *H*-theorem and the laws of classical mechanics is shown by two famous criticisms of the kinetic theory, the "reversibility paradox" and the "recurrence paradox." The first paradox is based on the fact that Newton's laws of motion are unchanged if one reverses the time direction, so that it would seem to be impossible to deduce from these equations a theorem that predicts irreversible behavior. In deriving the *H*-theorem, Boltzmann assumed that the velocities of two molecules are uncorrelated *before* they collide. Obviously they must be correlated *after* they have collided, so the theorem will not be correct if the time direction is reversed. The second paradox is based on a theorem of Henri Poincaré (French): if a mechanical system is enclosed in a finite volume, then after a sufficiently long time it will return as closely as one likes to its initial state. Hence *H* must return to its original value; if it has decreased during some period of time, it must increase during some other period. The time between successive recurrences of the same state for the molecules in 1 cc of air is much longer than the present age of the universe, so one does not have to worry about recurrences in any actual experiment. In spite of the two paradoxes, *H* is always found to decrease with time in actual experiments.

Other applications of the kinetic theory are discussed in the articles on AERODYNAMICS, BOLTZMANN'S DISTRIBUTION LAW, ELECTRICAL CONDUCTIVITY, LIQUID STATE, NUCLEAR REACTORS, and PLASMA.

L

LASER

"Laser" is an acronym for *l*(ight) *a*(mplification by) *s*(timulated) *e*(mission of) *r*(adiation). This device is identical in theory of operation to the MASER except that it operates at frequencies in the optical region of the electromagnetic spectrum, rather than in the microwave. Laser operation has been demonstrated at wavelengths from 3000 to over 1 000 000 Å or from 0.3 to 100 μ . By common usage, these devices are all called lasers, although more descriptive terminology utilizes ultraviolet maser, optical maser, infrared maser, etc. Although the original microwave maser offers an extremely stable frequency source, its main use is as an amplifier with extremely low noise output. In contrast, the main significance of the laser is its ability to produce a single frequency at high intensity in the optical region, a feat heretofore impossible at these frequencies. Not only may the output be a single monochromatic wave, but the wave may be coherent, or in phase, over the whole surface of the radiator. In this mode of operation, the laser is actually an oscillator whose output depends upon the selective amplification of one of the single frequency modes of the resonant cavity containing the active laser medium.

Following the development of the microwave maser, Schawlow and Townes in 1958 proposed that optical maser action could be obtained by placing an active medium in an optical cavity. The medium would be a gas or solid which was excited electrically or by light in such a manner that any optical wave present would be amplified as it moved through the material. The cavity was proposed to be a Fabry-Perot resonator—two plane parallel reflecting plates with a small transmission through which the radiation might escape. Upon excitation of the material, light will be emitted with a band of frequencies determined by the particular material. In addition, the direction of emission will be nominally random. In the presence of the cavity, some of the waves will escape after several back and forth reflections from the parallel plates, "walking off" the edge of the reflectors. Those waves which travel normal to the walls will remain in the cavity and be amplified provided they reinforce each other after each round-trip reflection at the two surfaces. This reinforcement or resonance is only satisfied if the spacing of the plates is an integral multiple of one-half the wavelength in the medium. Thus, after a

short time, only that frequency which satisfies the resonant condition and those waves traveling normal to the reflector will build up to an appreciable intensity. The resultant light which is partially transmitted through one of the reflectors will thus be a single frequency or several discrete frequencies if there is more than one cavity resonance within the band of frequencies emitted by the laser material. In addition, the wave front will be in phase across the surface of the reflector since waves striking the surface at normal incidence are amplified most strongly. The resultant beam will then be diffraction limited, i.e., the beam will spread by an angle in radians given approximately by the ratio of the wavelength to the diameter of the beam. In actual practice, single-mode operation is obtained only under special conditions. Generally, several frequency modes are present due to the multiple resonances of the cavity and numerous "off-axis" modes are found which correspond to resonant waves which travel at small angles from the normal to reflectors. These waves "walk off" so slowly that they still are amplified appreciably. Refinements of the simple cavity proposed by Schawlow and Townes consist of concave reflectors which decrease the diffraction losses or several parallel reflectors which limit the oscillation to a frequency common to each pair in the set.

The key to successful laser operation is of course the active medium which amplifies the wave. Qualitatively, a material which fluoresces or exhibits luminescence is an obvious candidate. In fluorescence, electrons are excited to an upper-energy state by short-wavelength light such as ultraviolet, while luminescence is produced by passing an electron current through the medium, such as in a gaseous discharge. In either process, stimulated emission can occur only if more electrons are produced in the upper-energy state than in the lower or terminal state for the radiating transition. In this case, an incident photon will stimulate further transitions and amplification will result. If the final state were more heavily populated, then the photon would cause more upward or absorbing transitions and the net effect would be absorption.

The first optical maser was demonstrated by Maiman of Hughes Research Laboratories in 1960 using ruby, which is single-crystal aluminum oxide "doped" with chromium impurities. By applying semitransparent reflective coatings on

the ends of a rod about 2 inches long, he made the cavity and the crystal an integral unit. Then, exposure to an intense exciting light from a xenon flashtube was found to invert the population between the red-emitting level and the ground or lowest-energy state of the electrons. The result was a burst of intense red light, emanating in a beam through the end reflectors. This was the first and is still one of the most powerful lasers. Advances in the art since that time have resulted in energies per pulse of the order of 1000 joules or watt-seconds. Peak powers are as high as 500 000 kW in short pulses of the order of 10^{-8} seconds. Because of "off-axis" modes and multiple resonances, the output is not a single-frequency, single plane-wave mode, but generally consists of the order of 100 separate modes. The beam is still quite narrow, being the order of 1 milliradian or 0.05 degrees. As a comparison with conventional light sources, the energy radiated from 1 cm² of the brightest flash lamp is less than 10 kW and is distributed over the entire visible spectrum. In addition, the radiation is incoherent and is spread out uniformly in all angles from the source. Thus, the directivity and spectral purity of the laser source are many orders of magnitude superior to that of an incandescent source. The ruby laser suffers from a low efficiency, about 1 per cent, and except with elaborate cooling systems, only operates on a pulsed basis. Other crystalline or glass systems with impurity ions have been developed, which yield wavelengths from the ultraviolet to approximately 3μ wavelength in the infrared. None of these are as powerful as ruby with the exception of glass doped with neodymium, or rare earth ion, which is comparable in power and radiates at 1.06μ in the near infrared, but with a broad distribution of spectral lines.

Historically, the next development came in 1961 when Javan, Bennet and Herriott demonstrated laser action in a gaseous discharge of helium and neon. Again, the parallel-plate reflector cavity was used but this time with a spacing of several feet. Later, concave mirrors were used to decrease the loss of energy out the sides of the cavity. This device operates continuously and delivers power at levels up to one watt. Pulsing the gas discharge yields peak powers as high as 100 watts. The first laser radiated at 1.15μ in the infrared, while further development with different gases has yielded outputs from the ultraviolet to 33μ or 0.33 mm in the far infrared. In contrast to the ruby laser, the gaseous laser beam may be diffraction limited and the frequency is pure, i.e., oscillation may be limited to one mode. By careful design, the frequency may be stabilized to a few thousand cycles per second or approximately one part in 10^{13} . The gas discharge is excited either by short-wave rf power or by a dc current supplied by internal electrodes in the discharge tube. Here the population inversion is produced by electron and ion collisions with the radiating atom. Again, as in ruby, the operating efficiency is low, less than 1 per cent.

The third main type of laser utilizes a solid

material, in this case a semiconductor. Here the electron current flowing across a junction between *p*- and *n*-type material produces extra electrons in the conduction band. These radiate upon making a transition back to the valence band or lower-energy states. If the junction current is large enough, there will be more electrons near the edge of the conduction band than there are at the edge of the valence band and a population inversion may occur. To utilize this effect, the semiconductor crystal is polished with two parallel faces perpendicular to the junction plane. The amplified waves may then propagate along the plane of the junction and are reflected back and forth at the surfaces. The gain in the material is high enough so that the reflection at the semiconductor-air interface is sufficient to produce oscillation without special reflective coatings. The first such device used gallium arsenide and radiated at 8400\AA or just beyond the visible region in the infrared. This laser was developed by groups at General Electric, International Business Machines, and Lincoln Laboratory in 1962. The efficiency is high, about 40 per cent, and the power source is low-voltage direct current. One shortcoming is the requirement of liquid nitrogen cooling (77 K) to maintain power output and efficiency. Powers as high as 3 watts continuous have been produced. The cavity in this case is extremely small, the reflector spacing being less than a millimeter. As a result, it is fairly easy to limit the oscillation to one frequency mode although small irregularities in the junction prevent coherence over the full width of the narrow radiating junction strip. The compactness and efficiency of the semiconductor laser make it particularly attractive for systems use. Wavelengths as long as 12μ and as short as 6300\AA have been generated using different semiconductors such as indium arsenide, indium phosphide, indium antimonide, or alloys such as gallium arsenide-phosphide.

Lasers have also been operated in liquid media, utilizing rare earth ions in such organic hosts as chelates. The most significant liquid laser utilizes a different principal than those above, depending upon stimulated Raman scattering. Raman laser action was discovered by Woodbury in 1962 using a ruby laser and nitrobenzene. Here the laser excites the nitrobenzene, which in turn shows amplification at a frequency displaced from the ruby line by the vibrational frequency of the molecule. There is no true inverted population in this case. The incident photon is scattered by the molecule which absorbs an amount of energy determined by its vibrational energy. The molecule is left in an excited state and the scattered photon is frequency shifted by the energy loss. This process may be stimulated, since the rate at which the scattered photons are produced is proportional to the number of photons already present in the cavity at the scattering wavelength. As in the normal stimulated emission case, the frequency and phase of the output wave are identical with the wave which stimulates the scattering. The Raman laser normally operates

using the Stokes line, or the wavelength corresponding to the loss of one vibrational quantum. Other modes of operation utilize the second or third Stokes lines corresponding to double or triple vibrational absorptions. Similarly, higher-order effects in the medium may produce a series of anti-Stokes lines which correspond to vibrational energy being added to the initial energy of the photons from the driving laser. The wavelength range of Raman lasers using different liquids is from the visible to the near infrared.

The high instantaneous powers quoted for ruby are obtained by using the "Q-switched" mode of laser operation. This technique, due to Hellwarth and McClung, uses a cavity resonator whose reflectivity or "Q" may be controlled externally. The laser, usually ruby, is first excited by the flash lamp while the cavity is in a state of low reflectivity and thus low feedback. As a result, the inverted population reaches an extreme value before oscillation occurs. At the peak of inversion, the reflectivity is "switched on," and the resultant high reflectivity produces an intense burst of energy which almost completely depopulates the high-energy states in a time of the order of 10^{-8} seconds. The switching is accomplished either by a Kerr electro-optic shutter in the cavity or by rotating one of the mirrors so that it is lined up parallel with the opposite reflector at the optimum time during the flash lamp pulse.

LENS

A lens is any element that focuses light to form images. Many lenses are found in nature. Ice crystals, waves on the surface of water, and all the eyes of humans and animals are examples of lenses. These lenses have one or more curved surfaces and are made of a transparent material. Manufactured lenses are usually made out of glass or crystal material. The simplest lens consists of two ground and polished spherical surfaces. A line connecting the centers of the two spheres is called the optical axis of the lens. The lens is edged to form a cylindrical surface centered on the optical axis. The spherical surfaces may be convex or concave, resulting in lenses which are positive refracting or negative

refracting. A positive lens collects the light from a distant object and focuses it to a real image. The negative lens disperses the light and causes it to diverge from a virtual image. Positive and negative elements are used in combinations to form optical lens systems. The optical axes of each of the lens elements usually coincide to form centered optical systems. Most optical systems are designed to be centered optical systems, but in manufacture the centering is seldom perfect, so the system will have various degrees of defective performance.

Spherical surfaces are usually used in optical systems because of stringent requirements on the manufacture of optical elements. In order to perform properly, a given surface in an optical system often has to coincide with the prescribed surface to within a few millionths of an inch. Such extreme tolerances can be achieved on spherical surfaces because spheres may be ground and polished with self-correcting techniques.

A few lenses have been made using non-spherical surfaces, but they usually have rotational symmetry around the optical axis. These surfaces are called rotationally symmetric aspheric surfaces. Aspheric surfaces of this type are difficult to generate so they are used infrequently.

Some lenses are made with cylindrical and toric surfaces. Spectacle lenses often have surfaces of this type. It is practical to use aspherics in spectacle lenses because the beam of light entering a person's eye is small in diameter. The performance requirements are therefore not great. Cylindrical or toric surfaces are seldom used in telescopes, or microscopes of high performance.

There are many types of glass used in optical lenses. Some glasses are more dispersive (see REFRACTION) than others. By combining positive and negative lenses of different glass it is possible to correct for chromatic aberrations.

Theory of the Lens. Most of the performance of a lens or lens system may be understood by considering that light travels as rays in straight lines until it encounters a change of index of refraction. The light is then refracted according to Snell's law (see REFRACTION). Light is emitted from a point source of light in the object as a diverging beam of rays. A lens is able to collect these rays and refocus them to an image point (see Fig. 1).

With analytical geometry, one may derive equations for calculating the path of any ray as it passes through the optical system. The procedure is called ray tracing. The mathematical equations used to trace rays are long and complicated, and have to be computed with many significant figures. Prior to the use of modern digital computers, the design and analysis of lens systems was a long tedious job. An average lens design required many months of calculation. Today most of these calculations are done on large computers, and few people need to be concerned about being able to ray trace.

Paraxial Rays. Paraxial rays pass through the center portion of the lens and the assumption is made that the object points are close to the optical axis. The ray-tracing equations for

FIG. 1. A diagram showing how a lens collects diverging rays and focuses them at an image point.

paraxial rays are simple, and by using the paraxial approximation, many useful theorems for lens performance may be worked out.

In the paraxial region, any optical system may be described by locating six cardinal points along the optical axis. Once these cardinal points are known, the position and size of the image of any object may be computed from the following formulas (see Fig. 2).

$$m = \frac{y_k}{y_0} = -\frac{z'}{f} = -\frac{f'}{z} \quad (1)$$

$$zz' = ff' \quad \text{and} \quad \frac{f}{s} + \frac{f'}{s'} = 1 \quad (2)$$

$$f/n_0 = f'/n_k \quad (3)$$

$$P_1N_1 = P_2N_2 \quad (4)$$

$$P_1P_2 = N_1N_2 \quad (5)$$

$$F_1N_1 = f' \quad (6)$$

$$N_2F_2 = f \quad (7)$$

P_1 and P_2 are called the first and second principal points. N_1 and N_2 are called the first and second nodal points. F_1 and F_2 are the first and second focal points. f and f' are the front and back focal lengths. n_0 and n_k are the indices of refraction in the object and image space.

The following terms are commonly used in connection with lenses:

Field of View. The field of view usually refers to the half angle subtended by the object as seen from the first principal point P_1 . For example, it would be $\tan^{-1}(y_0/S)$ in Fig. 2. When specified for a lens, it usually refers to the maximum size

of object which may be imaged by the lens. Optical designers tend to describe the field of view by its half angle, as shown in Fig. 2. Marketing firms often refer to the full field which is twice the half angle. If not clearly stated, confusion over this term may result.

Relative Aperture. This refers to the half angle of the cone of rays converging to the axial image point. The sine of this angle is often called the numerical aperture and is written NA . If NA is large, the lens collects a large cone of light and focuses it on the image. Another way to describe this NA is to use the term f -number. The f -number of a lens and the NA of a lens are related by the following equation

$$f\text{-number} = \frac{0.5}{NA}$$

Aperture Stop. The aperture stop in a lens system is a diaphragm which determines the NA of the lens.

Lens Aberrations. Lens designers attempt to combine elements and glass types to reduce the lens aberrations. All points in the object should be imaged as points in the image and should be located at or very near the position predicted by the paraxial rays. In lenses of large relative aperture and field of view, there are usually several residual aberrations that designers are unable to eliminate. There are the following types of aberrations:

- (1) Spherical
- (2) Coma
- (3) Astigmatic
- (4) Field curvature
- (5) Distortion
- (6) Axial chromatic aberrations
- (7) Lateral chromatic aberrations.

These aberrations are corrected by using combinations of positive and negative elements. There are two general principles one may use as guide lines in correcting optical systems. (1) A closely spaced positive and negative lens with the aperture stop in contact may be corrected for spherical aberration, coma, axial and lateral chromatic aberration and distortion. (2) It is necessary to use positive and negative lenses with appreciable air space between them to correct field curvature and astigmatism.

There are many conflicting requirements in lens systems. Lenses of large relative aperture usually are designed to cover small fields of view.

FIG. 2. Diagram showing the location of the six cardinal points in a lens system.

A large field of view normally dictates a small relative aperture. Wide fields and large aperture may be realized by using many elements or by compromising some of the image quality. For example, lenses of 140° total field working at $f/2$ are available, but they are complex and have large amounts of distortion. Periscopes allow one to look through a long pipe and see a wide field at high magnification, but there is always some residual chromatic aberration and field curvature left in the design.

Lenses are usually designed for specific applications, and the designer has made a careful balance between conflicting requirements. It is seldom that a lens designed for one application will perform optically in another. In the past there was a tendency to misuse lenses, because it was difficult to design a new system. Today it is easy to obtain a new design. It is still expensive to build a new prototype design. Optical shop practice has not yet been appreciably affected by our modern technology. This is partly because there has not been sufficient economic pressure to stimulate the investment in equipment, but it is also because the tolerances are still beyond the capabilities of modern automated machine tools. The next few years should see many changes in the optical industry, and it is expected that new systems will be much more readily attainable. With this improvement in optical shop capability, we will see many improvements in optical system capabilities because optical systems will be designed for specific tasks instead of for general use.

Lens Testing. A designer specifies a set of curvatures, thicknesses and optical glasses for a nominal design. The work shop makes the lens to these specifications within certain tolerances. The final lens must then be tested to make sure that the over-all performance is as expected. It is rare indeed that a lens performs exactly as computed. It is then necessary to determine if the difference is negligible and, if not, what to do about it. First, one tests the complete assembled lens and attempts to predict the performance. By studying the defective image, it may be possible to locate the sources of error. The tests consist of studying the light distribution in the image of a point source. This is done on a lens bench or testing interferometer. Sometimes it is possible to locate the source of error by testing the over-all system, but usually the lens system is disassembled and all the lens surfaces, spaces and centering are checked separately.

Lens Types. There are several optical systems which may be classified as types. There is considerable overlap between the types, but there is some value in the following classification.

Microscope Objectives. Microscope objectives are used to magnify small objects. They are usually used with a microscope eyepiece. Microscope objectives range in focal lengths from 2 to 48 mm and are used at magnifications ranging from 1000 to $5\times$. The high-power objectives are made up of many small elements. Some of the lenses are only a few millimeters in diameter. The lens

making and mounting procedures for such small lenses are quite different from larger elements.

Telescope Objectives. Telescope objectives are used to view distant objects. Telescope objectives have a wide variety of focal lengths and diameters. They are usually corrected precisely for spherical aberration, coma and axial chromatic aberration. Since telescope objectives cover small fields of view, astigmatism and field curvature usually are not corrected. Telescope lenses of large diameter (20 inches or more) become afflicted with chromatic aberration which cannot be corrected, so many of the large telescopes used by astronomers are mirrors instead of lenses.

Telescope objectives are used in binoculars, opera glasses, surveying instruments, gunsights, and many laboratory instruments.

Periscopes. Periscopes are used to enable one to look through a long tube. The submarine periscope is one well-known example, but there are many other types used in industrial and medical instruments. Gastrosopes and cystoscopes are examples of periscopes used in medical instruments. Periscopes are made up of a train of telescope objectives and eyepieces.

Camera Objectives. By far the largest class of optical lens systems would be classified as camera lenses. They are used to record images on films as in common landscape cameras, but today they are also used with many other types of image recording systems such as television image tubes, electrostatic plates, etc. The distinguishing features of camera lenses are wide field and large aperture. Usually the image is located on a flat image plane. Camera lenses range in complexity from a single meniscus lens to systems with more than ten elements. Camera lenses cover such a wide range of uses that one could claim all lenses to be a form of camera lens. For example, a long focal length lens used on a 35-mm camera may actually be very similar to a telescope objective.

Eyepieces. Eyepieces are quite clearly a distinctive class of optical lens system. Eyepieces are designed to match the sensitivity and physical requirements of the human eye. For example, the eye is sensitive in the visual part of the spectrum so eyepieces are designed for this range of wavelengths. An eyepiece must also be located with its aperture stop in an external position so that the observer's eye may be located within it. This requirement imposes serious limitations on eyepieces, and they are seldom useful in any other applications.

Magnifiers are essentially eyepieces except they are designed to view opaque material while an eyepiece is designed to view an aerial image formed by an objective.

Condensers. Condensers are used to collect and focus large amounts of light. They are found in projectors and substages of microscopes. A searchlight mirror is a form of a condenser. The numerical aperture of a condenser is usually very large, and for many applications, the image-forming properties are not important. Condensers are often made, therefore, with low-quality surfaces. Some condenser lenses are

molded. Condensers are usually placed close to an intense light source which heats and cracks the lenses if made of glass. Condensers are often made out of quartz because of its ability to withstand heat. Aspheric condenser lenses are common in condensers. With some of the modern high-intensity light sources, it is necessary to correct for the image errors in order to obtain uniform illumination.

LIGHT

Light is a form of electromagnetic energy. It has a physical character similar to that of radiowaves. In order that the human eye may get the sensory perception of light, the electromagnetic waves entering the pupil should have a wavelength λ between 4000 and 7000 Å ($1 \text{ Å} = 10^{-8} \text{ cm}$). The wavelength of a wave is inversely proportional to its frequency ν . The product of the two quantities equals the velocity of propagation. For light in vacuum one has $c = \nu\lambda = 3 \times 10^{10} \text{ cm/sec}$. The frequency of light waves is therefore almost a billion times higher, their wavelength a billion times shorter, than the waves of standard radio broadcast bands. The perception of color depends on the distribution of the electromagnetic energy over the visible wavelengths. White light is a superposition of waves at many frequencies. It can be decomposed into its monochromatic spectral components by a prism or other spectral apparatus. The violet end of the spectrum is near 4000 Å, the red end near 7000 Å. Whereas light in its narrow definition should be confined to this relatively narrow portion of the electromagnetic spectrum, it is customary to extend the definition to the ultraviolet and infrared portion of the spectrum. One sometimes speaks loosely of ultraviolet and infrared "light," although electromagnetic waves at these frequencies are not detected by the eye. The human mind and hands have, however, devised a large variety of instruments by which such invisible radiation can be detected and measured. Photographic plates can be made sensitive to x-rays, with a wavelength shorter than the ultraviolet, or to the much longer wavelengths of the infrared. Geiger counters can detect electromagnetic radiation of very short wavelengths (γ -rays and x-rays). Photoelectric cells are sensitive in the ultra-violet and visible portion of the spectrum. Photoconductivity can

be used to detect infrared radiation. At still longer wavelengths, the microwaves and radiowaves are detected by diode detectors in appropriately arranged microwave and radioreceivers. All these types of radiation can also be converted into heat by absorption in a blackbody, i.e., a material that can absorb radiation at all wavelengths. The radiation can be felt as heat, if it is absorbed by the human skin.

The study of the human eye as a detector of light is the task of *physiological optics*. The impression of light is not necessarily always connected with the simultaneous presence of electromagnetic energy at the retina. We see "stars" from a heavy mechanical blow in the dark. The impression of light is retained for about 0.1 second after the light source is shut off. This fact is made use of in the movies to create the impression of motion by a series of still images. The eye is a detector with a relatively long response time. Photoelectric cells can react more than a million times faster. Color vision is also subject to physiological peculiarities which are quite complex (see COLOR and VISION AND THE EYE).

The property of light which is most immediately accessible to observation is its propagation along straight lines (shadows). The law of REFLECTION also dates from Egyptian antiquity. If light rays pass from one medium to another, their direction is changed according to the law of REFRACTION. If the light in medium 1 propagates with a velocity v_1 and makes an angle θ_1 with the normal to the boundary between media 1 and 2, the direction θ_2 in medium 2, with a velocity of propagation v_2 is given by Snell's law, $\sin \theta_1 / \sin \theta_2 = v_1 / v_2 = n$. The constant n is called the relative index of refraction of medium 2 with respect to medium 1. These three laws are the basis of *geometrical optics*. This branch of the science of light describes the paths of light rays, the formation of images by mirrors and lenses, the action of telescopes, microscopes, prisms and other optical instruments.

The wave character of light becomes apparent by more refined observations. The phenomena of diffraction, interference and polarization are the subject of *physical optics*. Diffraction describes how waves are bent around obstacles. They represent corrections to and deviations from the laws of geometrical optics. These effects become pronounced only when the material has a characteristic dimension comparable to the wavelength of the wave. When light waves reach the same point along different paths, the resulting intensity may be smaller than that produced by each individual wave separately. The relative phases of the waves may be such that they interfere destructively, when the arrival of one wave with maximum positive deflection coincides with that of another wave with maximum negative deflection. Observations of light in crystals of calcite (iceland spar) first showed that there are two different modes of vibrations for each direction of propagation. These are called the two transverse modes of polarization.

All phenomena of geometrical and physical optics are described consistently by Maxwell's

equations of electromagnetic theory. Optical phenomena are, therefore, closely related to other electric and magnetic phenomena. Around 1900 the prevailing opinion was that the wave character of light was unambiguously established and the nature of light well understood.

There was, however, a mathematical difficulty with the intensity of radiation at ultraviolet and higher frequencies. The photoelectric effect could also be interpreted only by considering light to have a quality of particles. The number of electrons emitted from a photosensitive surface is proportional to the intensity of the light. The energy of the individual electrons is, however, determined by the light frequency. This led to the postulate of light quanta with energy $h\nu$, where h is Planck's constant. This duality in nature, in which "wave-like" and "particle-like" properties are combined, is described without internal contradiction by quantum mechanics. The combined "particle and wave" character of light is revealed by the combination of properties of the light sources, the electromagnetic field describing the light waves, and the detectors.

The study of the interaction of light waves with matter in the sources and in the detectors is the subject of SPECTROSCOPY. This is a wide field which encompasses atomic and molecular spectroscopy, parts of solid-state physics and photochemistry. The quantum theory was largely developed on the basis of spectroscopic data. A light quantum is emitted by an excited atom, molecule or other material system, when an electron in such a particle makes a transition or "quantum jump" from a state with higher energy to a state with lower energy. The energy difference between these states is equal to the quantum energy $h\nu$. Similarly, the absorption of light quanta is accompanied by an electronic transition from a state with a lower energy to a state with an energy higher by an amount $h\nu$. In this manner, the frequencies of spectral lines are characteristic for the electronic energy levels in each material. The frequency of the light may be said to correspond to the frequencies of the vibrating charges or oscillators, which are represented by the electrons.

Light sources are thus bodies with a sizeable population of electrons in excited states. This may be accomplished by raising the temperature of the material. The most important source of light is the sun. The moon and other planets are visible only because they reflect sunlight, just as all other objects on the earth which we can see by daylight, but not at night. The sun is a star. In stars, the temperature is maintained at a very high temperature by nuclear reactions.

Man-made light sources range from the primitive fire, candles, and oil and kerosene lamps to the electric light bulb, fluorescent gas-discharge tubes, arcs, etc. In early sources, the material particles of smoke or wick were heated by the chemical reaction of oxidation or burning; in the incandescent electric lamps, a wire is heated to a very high temperature by an electric current. There are so many energy levels in these luminous

solid materials or gases at high pressures that the emitted light is white and contains essentially all frequencies. The higher the temperature, the more radiation is emitted and the higher the average frequency of radiation. It should be realized that most of the energy is emitted as invisible (infrared) radiation, even in the best incandescent lamps. Hot gases in flames may also emit sharp spectral lines characteristic of the atoms occurring in the flame. The yellow color which arises when kitchen salt is sprinkled in a flame is due to the characteristic yellow spectral line of sodium atoms.

In gas discharge tubes, atoms or molecules are excited by collisions with electrons in the ionized gas. The energy is provided by the generator which provides the voltage necessary to maintain the discharge current. An arc is a discharge in air or in a high-pressure vapor. Mercury and sodium discharges are used for street lighting. Fluorescent tubes for office and home lighting use a gas discharge with a substantial amount of ultraviolet components. This ultraviolet light excites electrons in fluorescent centers on the walls of the tube. The electrons drop immediately from the highly excited state to an intermediate state with a lower energy. From this state they finally drop down to the original ground energy level with the emission of visible light. Gas discharges at relatively low pressure may serve as spectroscopic sources to study the emission spectra of atoms, ions and molecules. From the relationship between the energy levels and the frequency of radiation, it follows that a material, when heated, can emit precisely those frequencies which it absorbs, when it is in the lowest energy level at low temperature.

All these light sources are incoherent in the sense that there is no phase relationship between the light waves emitted by the different atoms in the source. This is quite different from the property of the usual sources of electromagnetic radiation at lower frequencies. In the oscillator tubes of radio- or microwave transmitters, all electrons move and vibrate in step with each other. The analogy between light and low-frequency electromagnetic radiation raises the question, "Can coherent light sources be constructed?" Recently such coherent light sources have been developed. They are characterized by the emission of a highly directional, highly monochromatic light beam of high intensity. They are called LASERS because they are based on light amplification by stimulated emission of radiation. In the conventional sources, all light is emitted spontaneously. In lasers, the original spontaneously emitted light forces the other excited atoms to emit their radiation in step, or coherently. If stimulated emission thus dominates the spontaneous emission, a laser results. This requires a high concentration of excited atoms and a sufficient feed back mechanism of light by mirrors. In its simplest form a laser consists of a gas discharge in a tube of suitably chosen dimensions and gas pressure between a set of parallel mirrors. Because the atoms in the laser source all act constructively in step, these sources provide a more efficient means to transmit light energy.

The high light intensities available in focused laser beams have led to the development of the branch of nonlinear optics. The optical properties of materials are different at high intensities, because the electronic oscillators are driven so hard that anharmonic properties become evident. A typical effect is the harmonic generation of light in which red laser light is converted into ultraviolet light at exactly twice the frequency, when the high-intensity beam traverses a suitable crystal such as quartz. It should be possible to duplicate at light frequencies all nonlinear effects known from the field of radio communications, such as modulation, demodulation, frequency mixing, etc. It is no longer correct to say that the propagation of a light wave is independent of the presence of other light waves. At high intensities, there is a noticeable interaction between light waves of different frequencies.

The combination of the laws of quantum mechanics and electromagnetic theory gives a consistent description of the generation, propagation and detection of light. Since these same laws also describe many other properties of matter such as electronic structure, chemical binding, electricity and magnetism, etc., it may be said that the nature of light is well understood. In this context, it is not necessary and not even desirable to pose the question, "What is it, precisely, that vibrates in a light wave in vacuum?" The electromagnetic fields acquire meaning only through their relationships with detectors and sources. Human knowledge or understanding is here used in the operational sense that a relatively simple framework of physical concepts and mathematical relationships exists, which gives an accurate description of the wide variety of optical phenomena at present accessible to observation or verification in experimental situations. The following references will introduce the reader to the vast literature of optics and spectroscopy.

LIGHT SCATTERING

When a beam of light falls on a particle, part of this incident beam is diverted from its original path; that part which is diverted and not absorbed is *scattered*.

Light scattering is a very familiar phenomenon. The colors of visible objects (other than light sources) are determined by the wavelengths which they scatter most effectively. Scattering by small particles was first studied experimentally in great detail by Tyndall (1869) in connection with the blue of the sky and has become known as *Tyndall scattering*.

Classical physics is appropriate for the description of most light-scattering phenomena. Thus, light scattering is explained in terms of the forces exerted by the electromagnetic field on the electronic charges which all matter contains. The oscillating electromagnetic field of the incident light exerts a periodic force on each electronic charge, causing it to execute harmonic motion at the light-wave frequency. It is the fact that an oscillating charge radiates in all directions (except along the line of its motion) which accounts for the scattering. The intensity of the radiation scattered from a particle will be large in directions for which the radiation from the individual elements of the particle interferes constructively, and small in directions in which it interferes destructively.

For particles comparable in size to the light wavelength, the amount of energy scattered as well as the angular distribution of the intensity and polarization of the scattered light are influenced by the distribution of induced oscillating charge within each scatterer. Any correlation which may exist between the positions of the scatterers also affects the extent to which the radiation interferes constructively or destructively to make up the resultant scattered field. Thus, in principle, light scattering provides a tool for the investigation of the number, size, shape, internal structure and orientation of particles and their mutual interactions.^{1,3}

The problem of relating the light scattering to these properties and vice versa has proved too difficult for solution in general. This is not surprising, for it would be necessary to solve Maxwell's equations with the proper boundary conditions for each particle. Many important cases have been solved, however, subject to certain approximations. Widest success has been achieved for *single scattering*, i.e., for particles sufficiently dispersed that radiation scattered by any one particle can be considered to escape from the medium without being further scattered by other particles. Multiple scattering is relatively difficult to treat and is usually avoided when possible.^{2,4}

In many cases, light scattering is related to the composition and structure of the medium in a way similar to x-ray scattering. The criterion which must be satisfied is that the electromagnetic field within the scatterers should be closely approximated by the unperturbed incident field,

just as in the x-ray case. Light scattering under this approximation is widely known as *Rayleigh-Gans* scattering. It is applicable if the phase shift for radiation passing through a particle is not too different from the phase shift which would occur for radiation passing through the same distance in the surrounding medium.^{1,3} When the Rayleigh-Gans approximation is valid, the angular intensity distribution of the scattered light is related, as in x-ray scattering, to a "form factor" which describes structure of the individual scatterers and to a "radial density function" or correlation function which describes the order in their spatial arrangement.^{2,3}

If the particles are less than about 1/10th of the light wavelength, and if their index of refraction is near to that of their surroundings, only the induced electric dipole radiation is important. Lord Rayleigh (1871) explained Tyndall's principal results in terms of the intensity and polarization of the induced electric dipole radiation. This type of scattering has since become known as *Rayleigh scattering*.

Rayleigh scattering is of particular importance. If the particles are dispersed at random (molecules of an ideal gas or widely dispersed macromolecules in an essentially homogeneous solution), the individual particles may be regarded as independent sources. In this event, the total scattered intensity is merely the sum of the intensities scattered by the individual particles. The special case of isotropic particles and unpolarized light is both simple and illuminating. The Rayleigh formula is

$$\frac{\text{Intensity of scattered light}}{\text{Intensity of incident light}} = \frac{8\pi^4 N \alpha^2 (1 + \cos^2 \theta)}{\lambda^4 r^2}$$

where N is the number of particles, α is their polarizability, θ is the angle of scattering, λ is the wavelength, and r is the distance from the scattering system to the point of observation (where $r \gg$ any relevant dimension of the scattering system). Thus, Rayleigh scattering from independent particles is proportional to the number of particles and is quite insensitive to their shapes. When the total mass of scatterers is known, it provides a tool for the measurement of molecular weight.

As we consider larger particles which begin to violate the criterion that their dimensions be very small compared with the wavelength, the Rayleigh formula breaks down. This breakdown first appears at large scattering angles, where the destructive interference is first significant, and quickly spreads to moderate and small angles. Nevertheless, for scattering angles sufficiently near zero, the Rayleigh formula retains validity since for zero scattering angle the radiation from all volume elements within a particle is "in phase" regardless of the particle size. Thus, the Rayleigh formula is actually useful, when properly applied, over an extremely wide range of molecular weights (10^2 to 10^7).¹⁻³

For scattering from dense media such as liquids, it is important to recognize that the individual molecules can not ordinarily be treated

as independent scatterers. Perhaps the most direct formulation of the problem is in terms of the radial density function mentioned earlier. Often, however, this function is not of immediate interest and one would prefer to relate the light scattering directly to the thermodynamic properties of the medium. For Rayleigh scattering, this may be accomplished in a direct way through an ingenious approach due to Smoluchowski (1908) and Einstein (1910).^{2,3} This approach takes advantage of the fact that for molecules small compared with the wavelength and for intermolecular forces extending over distances small compared with the wavelength, the scattered field may be regarded as made up of radiation from elements of volume small enough that each element may be considered an electric dipole source and yet large enough that the elements can be considered to be independent of each other. If the index of refraction of every element were identical, the solution would be homogeneous and no scattering would result. But the index of refraction of an element will fluctuate according to the number of molecules it contains. The total scattering is found to be proportional to the mean square fluctuation in index of refraction which is related to the thermodynamic properties of the solution through free energy.

Up to this point, the frequency of the scattered light has been regarded as identical to that of the incident light. Actually, line broadening will occur due to a number of mechanisms. The line structure has been measured when highly monochromatic laser light is used and has been interpreted in terms of particle size.⁵ In general, the spectrum of the scattered radiation is found also to have relatively weak lines (or bands) which are absent from the incident light. They were first studied in detail by Raman (1928), and are known as the *Raman spectrum*.⁶ It is perhaps the only light-scattering phenomenon which must be explained by quantum theory.

LIQUEFACTION OF GASES

The liquefaction of all readily available gases has become a routine operation in industrial technology. Prominent among the reasons for converting a gas to a liquid are the net saving in cost of storing or of transporting a normally gaseous material in liquid form, the convenience and flexibility of providing very low temperature refrigeration to a multiplicity of sites of modest or intermittent consumption in the form of a low-boiling liquid, and the efficiency attainable in the separation of the components of a gaseous mixture by the partial liquefaction of the mixture, or its total liquefaction followed by rectification.

The transoceanic shipment of liquefied natural gas, the commercial distribution of liquid helium to scientific laboratories, and the production of pure oxygen and pure nitrogen from air are representative examples of the first, second and third reasons, respectively. The first and last examples currently operate on scales such that thousands of tons of liquid are produced daily.

To produce a cold liquid product from gaseous raw material at ambient temperature requires a heat pumping operation. Thermodynamic analysis gives the (unattainable) irreducible minimum work which must be expended in the heat pump, operating in an environment at temperature T_0 , to convert a unit mass of warm gas to liquid to be

$$W_{\min} = (H_{\text{liquid}} - H_{\text{gas}}) - T_0(S_{\text{liquid}} - S_{\text{gas}})$$

where H_{liquid} and H_{gas} are the enthalpies and S_{liquid} and S_{gas} are the entropies per unit mass of liquid product and gaseous raw material, respectively. These thermodynamically reversible works of liquefaction are listed for various of the "permanent" gases in Table I, which assumes that the starting material is gas at one atmosphere pressure and 300°K. In large-scale, practical operations, the actual work requirement will

range from ~3 times the minimum for a gas such as methane to ~15 times the minimum for helium.

TABLE I. MINIMUM WORK OF LIQUEFACTION OF VARIOUS GASES

Substance	Boiling Point (°K)	Work Required (kW-hr/lb)
Methane	111.7	.145
Oxygen	90.2	.080
Nitrogen	77.3	.096
Hydrogen	20.4	1.48
Helium	4.22	0.86

To achieve the minimum thermodynamic work requirement for cooling and liquefying a stream of gas, an infinite sequence of perfectly efficient refrigerators operating at successively lower temperatures ranging from ambient to the boiling point of the material would be required. Various approximations to this theoretical ideal have been developed.

Cascade Process. If the critical temperature of the gas which is to be liquefied lies well *above* the boiling point of some second fluid, whose critical temperature in turn lies above the boiling point of yet another fluid, and so on to some fluid which is condensable at ambient temperatures, then one can replace the infinite sequence of refrigerators of the thermodynamic ideal with this discrete series of liquid cooling baths.

The raw material is compressed to the pressure necessary to condense it at the temperature of the final refrigerant bath. The resulting liquid is expanded through a throttle valve, and the vapor which boils off in the throttling is recycled to conserve the refrigeration it represents. Such an arrangement is shown schematically in Fig. 1.

FIG. 1. Schematic arrangement for two-stage cascade.

The penalty in increased work over the thermodynamic minimum arises from the small number of steps in the sequence, with the attendant irreversible exchange of heat between the process gas and the much colder baths; from the throttling losses for the product liquid; and from the imperfect efficiency of *any* real refrigerator or compressor. In the simple liquefaction of any gas for which a cascade of refrigerants can be found, the economic performance of a cascade compares very favorably with any other process for truly large-scale operations.

For small-scale systems, the operational complexity and the equipment cost of a cascade are prohibitive.

Linde and Claude Processes. A stream of cold gas, flowing countercurrent to the process stream in a heat exchanger which establishes perfect thermal equilibrium between the two streams at every point along their path can substitute perfectly for the infinite sequence of refrigerators in the theoretical ideal system. The problem is just to produce the stream of cold gas (let alone to produce it with perfect efficiency) and to produce a refrigerator to extract the heat of vaporization from the product material at its boiling point.

Application of the first law of thermodynamics to the system shown in Fig. 2, consisting of a

FIG. 2. Adiabatic throttling flow system.

constant high-pressure source of fluid at P_1 which flows at constant rate through an insulated heat exchanger B, then through a throttling device C and back through exchanger B, leaving the exchanger against some constant low pressure, P_2 , at the *same* temperature at which high-pressure fluid enters, gives

$$H_1 + Q = H_2$$

H_1 and H_2 are the enthalpies per unit mass of fluid entering and leaving the system, respectively, and Q is the amount of heat *absorbed* by a unit mass of fluid in passing through the system. The initial and final kinetic and gravitational potential energies are assumed equal. H_1 will be smaller than H_2 for most gases at absolute temperatures

less than 8 to 10 times their normal boiling point and for initial pressures of several hundred to a few thousand pounds per square inch. At higher temperatures, H_1 will be larger than H_2 so that Q is negative—heat is *liberated* within the exchanger-throttle valve system. If the thermal insulation of the exchanger-throttle valve system is *perfect*, then for $H_1 < H_2$, the exchanger-throttle valve system and the circulating gas itself will be continually cooled until some of the circulating gas accumulates within the system as liquid and a new energy balance $H_1 = fH_{\text{liquid}} + (1 - f)H_2$ is attained. The fraction, f , of the entering gas accumulates within the system as liquid product with enthalpy H_{liquid} , and the fraction $(1 - f)$ returns through the exchanger as its refrigerant.

Carl von Linde, in 1885, was the first to couple the relatively feeble (40°C maximum for air expanded from 4000 psi to one atmosphere room temperature) Joule-Thomson cooling, produced by throttling a high-pressure gas and a regenerative heat exchanger, to give the very simple system which is capable of liquefying any gas except helium, hydrogen and neon, starting from room temperature—albeit with poor efficiency. For helium, hydrogen and neon, throttling at room temperature produces heating ($H_2 > H_1$). Sir James Dewar used a bath of liquid oxygen to precool compressed hydrogen to $\sim 90\text{ K}$ where $H_2 < H_1$. The cooled hydrogen was then fed into a simple Linde liquefier, and Dewar first liquefied hydrogen in this way in 1898.

Kammerlingh Onnes used a bath of liquid hydrogen boiling under vacuum near its freezing point to precool compressed helium to $\sim 14\text{ K}$ (where $H_2 < H_1$ for helium). The helium was then fed into a simple Linde liquefier, and Onnes first liquefied helium in 1908.

For any real system, whose thermal insulation leaks q units of heat per unit mass of entering gas and whose exchanger permits gas to leave the system at $T_2' > T_1$, the energy balance becomes

$$H_1 + q = fH_{\text{liquid}} + (1 - f)[H_2 - C_p(T_2' - T_1)]$$

Poor insulation (large q) and an inefficient exchanger (large $T_2' - T_1$) can easily reduce f to zero.

As the temperature of the gas entering the exchanger of a Linde liquefier approaches its critical temperature, the thermodynamic efficiency of the system as a refrigerator rises sharply. A simple Linde liquefier (commonly but improperly called a Joule-Thomson liquefier) is combined with any of several types of efficient auxiliary preliminary refrigerators and forms the final stage of almost every large scale liquefier in common use. Linde, himself, quickly modified the simple system to what in essence is a pair of simple liquefiers operating in cascade. The first (precooling) unit operates between a common initial high pressure and some intermediate pressure for optimum efficiency, rather than between the high pressure and one atmosphere. He also added a conventional ammonia refrigerator for precooling to further enhance efficiency.

It is possible to produce a cold stream of gas with relatively good efficiency by allowing compressed gas to expand in a reciprocating expansion engine, or in an expansion turbine. If the expansion engine is preceded by an efficient regenerative heat exchanger, relatively modest ratios of inlet pressure to exhaust pressure at the expansion engine will produce gas near its boiling point. The thermodynamic efficiency of such expanders commonly approaches or exceeds 80 per cent. A fraction of this cold exhaust gas can be used to refrigerate the feed stream to a simple Linde liquefier. Georges Claude in 1905 combined a reciprocating expansion engine with a simple Linde liquefier as shown schematically in Fig. 3 to produce an air liquefier of improved efficiency which became known as the Claude cycle.

Peter Kapitza combined a precooling bath of liquid nitrogen in sequence with a reciprocating

FIG. 3. Schematic arrangement Claude cycle.

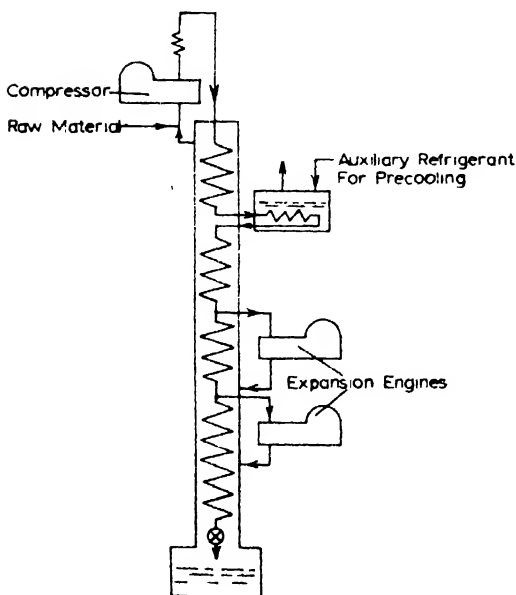

FIG. 4. Composite system for helium liquefaction.

expansion engine to precool compressed helium feed for a final Linde stage in 1934 and produced a Claude cycle liquefier which liquefied helium without the use of any auxiliary liquid hydrogen. Collins developed a similar machine which has been produced commercially in relatively large numbers. It uses a cascade of two expansion engines in a Claude cycle liquefier capable, when combined with liquid-nitrogen precooling, of producing ~8 liters of liquid helium per hour. The schematic arrangement is shown in Fig. 4. The same schematic arrangement of liquid precooling bath or baths followed by expansion engines all precooling the feed to a final Linde liquefier, could be used to describe in essence the large plants currently used for the liquefaction of hydrogen or helium.

LIQUID STATE

Liquid is the term used for a state of matter characterized by that of a pure substance above the temperature of melting and below the vaporization temperature, at any pressure between the triple point pressure and the critical pressure (see Fig. 1). The liquid state resembles the crystalline in the relatively low dependence of density on P and T , and resembles the gas state in the inability to support shear stresses (see reference to glasses below). Structurally the molecules are relatively close together but they lack long-range crystalline order. The mutual solubility of different liquids is also intermediate between the complete mutual solubility of all gases, and the relatively rare appreciable mutual solubility of pure crystalline compounds. Two liquids of similar molecules are usually soluble in all proportions, but very low solubility is sufficiently common to permit the demonstration of as many as seven separate liquid phases in equilibrium at one temperature and pressure (mercury, gallium, phosphorus, perfluoro-kerosene, water, aniline, and heptane at 50°C, 1 atmosphere).

Stability Limits. With the exception of helium and certain apparent exceptions discussed below, Fig. 1 gives a universal phase diagram for all pure compounds. The triple point of one P and one T is the single point at which all three phases,

FIG. 1

crystal, liquid, and gas, are in equilibrium. The triple point pressure is normally below atmospheric. Those substances, i.e., CO_2 , $P_t = 3885$ mm, $T_t = 56.6^\circ\text{C}$ for which it lies above, sublime without melting at atmospheric pressure.

From the triple point, the melting curve defines the equilibrium between crystal and liquid, usually rising with small but positive dT/dP , and presumably always with positive dT/dP at sufficiently high P values. The line is believed to extend infinitely without a critical point (it has been followed to $T \approx 16T_c$ for He, and calculations indicate that hard spheres would show a gas-crystal phase change). The gas-liquid equilibrium line, the vapor pressure curve, has dT/dP always positive and greater than the melting curve. The vapor pressure curve always ends at a critical point, $P = P_c$, $T = T_c$, above which the liquid and gas phase are no longer distinguishable. Since the liquid can be continuously converted into the gas phase without discontinuous change of properties by any path in the P - T diagram passing above the critical point, there is no definite boundary between liquid and gas.

The term *liquid* is commonly reserved for $T < T_c$, and "dense gas" is used for $T > T_c$. However, certain properties, such as the ability to dissolve solids, change rather abruptly at the critical density. In many respects, the dense gas resembles the low-temperature liquid of the same density more closely than it does the dilute gas.

The slope, dT/dP , of all phase equilibrium lines obeys the thermodynamic Clapeyron equation:

$$dT/dP = \Delta V/\Delta S = T\Delta V/\Delta H \quad (1)$$

with ΔV , ΔS , and ΔH the differences, for the two phases, of volume, entropy, and heat content or enthalpy, respectively. The quantity ΔH is the heat absorbed in the phase change at constant P . Since always $S_{\text{cr}} < S_{\text{liq}} < S_{\text{gas}}$ and usually $V_{\text{cr}} < V_{\text{liq}} < V_{\text{gas}}$, one usually has $dT/dP > 0$; the relatively rare cases, including water, for which $V_{\text{liq}} < V_{\text{cr}}$, at low pressures leads to $dT/dP < 0$ for the melting curve near the triple point.

Figure 1 gives the P - T boundaries of the stable liquid phase. Clean liquids can readily be superheated or supercooled, and in vessels having walls

to which the liquid adheres, they can be made to support negative pressures of several tens of atmospheres. Thus the properties of the metastable liquid can be investigated outside the limits shown in the diagram.

Two apparent exceptions to the universality of the phase diagram of Fig. 1 deserve mention. First, many of the more complicated molecules decompose at temperatures below melting or boiling, and the diagram is unobservable. Secondly, some liquids, notably glycerine and SiO_2 and many multicomponent solutions, supercool so readily that crystallization is difficult to observe. In these cases, there is a continuous transition on cooling to a glass, which has the elastic properties of an isotropic solid. The structure of the glass is qualitatively that of the high-temperature liquid, lacking long-range order. Since glass and liquid are not sharply differentiated, the term *liquid* is sometimes used to include glasses, although common parlance reserves liquid for the state in which flow is relatively rapid.

Quantum Liquids. The one real exception to the phase diagram of Fig. 1 is that of helium, Fig. 2. Both isotopes, He^1 and He^3 , have no

FIG. 2.

triple point, the liquid is stable to 0°K below about 20 atmosphere for He^1 and below about 30 atm for He^3 . The liquids have zero entropy at 0°K in both cases. This is also the only case in which isotopic mixtures form two liquid phases at equilibrium: the isotopic solution separating below 1 K. The isotope He^4 has itself two phases, He I above the dotted λ -line of the diagram, and He II with remarkable properties of superfluidity, second sound, etc., below the λ -line. The phase transition along the λ -line is second order; that is, whereas S and V are continuous, heat capacity and compressibility change discontinuously across the λ -line.

Although no completely satisfactory single theory of liquid helium has yet been formulated, one can say that most of the remarkable properties are qualitatively understood and are due to the predominance of quantum effects, including the difference in the statistics of the even and odd isotopes. Thus helium is the one example in nature of a quantum liquid, all other liquids

showing only minor deviations from classical behavior.

Structure. Considerable confusion in the description of liquid structure exists, due primarily to difficulties of precise formulation of verbal concepts. The geometric arrangement of any small number (say 10 to 12) of close lying molecules resembles the arrangement in the crystal, but the order rapidly disappears as larger groups are considered. Long-range order is lacking. The fact that numerical theories based on a lattice or cell structure have some success is evidence only that most properties depend on the configuration of near neighbors alone. Insofar as the arrangement of nearest neighbors is describable in terms of that of the crystal, the structure of the normal liquid is probably characterized best by a somewhat closer spacing than the crystal of the same molecules, the reduced density arising from a considerable number of vacancies in the lattice; the coordination number or number of nearest neighbors is lower than in the crystal. The exception is water, in which the low coordination number, 4, of the crystal, is increased by interstitial molecules in the liquid, leading to a higher density of the liquid.

Structural descriptions of this nature usually lack the possibility of precise formulation. It is, however, possible to define for any disordered array of molecules in three-dimensional space an arrangement of contiguous cells, each containing one and only one molecule, the faces of the cells being the loci of the midpoints of neighboring molecules. The statistics of the fraction of cells with n faces and of the distances of the faces from the molecules would give the fraction of molecules having a given number of nearest neighbors and the distance distribution of these in a precisely defined manner. Neither present experimental information nor present theories lend themselves to analysis in such terms.

The only clearly defined manner of describing liquid structure in use at present involves the concept of a set of probability density functions, ρ_n , for ascending numbers, n , of molecules. The function ρ_n depends on the vector coordinates $\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n$ of n molecules, and

$$\rho_n(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n) d\mathbf{r}_1, \dots, d\mathbf{r}_n$$

is defined as being the probability that in the liquid of definite P and T , there will be at any instant of time, one molecule at each position, \mathbf{r}_i , within the volume element, $d\mathbf{r}_i$. For a fluid, unlike a perfect single crystal, $\rho_i(\mathbf{r})$ is a constant independent of \mathbf{r} and equal to the number density: the number, ρ , of molecules per unit volume. The first significant member of the set is then the pair density function, $\rho_2(\mathbf{r}_1, \mathbf{r}_2)$, which depends only on the distance, $r = |\mathbf{r}_1 - \mathbf{r}_2|$, between the two molecules. At large distances $\rho_2(r \rightarrow \infty) = \rho^2$. This function can be found experimentally from the x-ray scattering intensities of the liquid (it is the three-dimensional Fourier Transform of the scattering intensity at angle θ vs $(4\pi/\lambda)/\sin(\theta/2)$). A typical plot is shown in Fig. 3. The area under

FIG. 3.

the ill-defined first peak integrated over $4\pi r^2 dr$ is the average number of nearest neighbors, and is of order 10 to 11 for normal liquids.

The quantity of dimensions of energy,

$$W_n(\mathbf{r}_1, \dots, \mathbf{r}_n) = kT \ln [\rho^{-n} \rho_n(\mathbf{r}_1, \dots, \mathbf{r}_n)]$$

can be shown to be the potential of average force of n molecules located at the positions $\mathbf{r}_1, \dots, \mathbf{r}_n$. That is, if there are n molecules at these positions there will be some average force, \bar{f}_i , along the x -coordinate of molecule i . This average is the sum of the direct force due to the other $n-1$ plus the average of a fluctuating force due to the others, whose average position is affected by that of the n specified ones. This average force is

$$f_{xi} = -(\partial/\partial x_i) W_n(\mathbf{r}_1, \dots, \mathbf{r}_n)$$

One frequently assumes that W_n is a sum of pair forces only,

$$W_n(\mathbf{r}_1, \dots, \mathbf{r}_n) = \sum_{n \geq i > j \geq 1} W_2(\mathbf{r}_{ij})$$

although this assumption is known to be only approximate. With this assumption, the pair average force potential, $W_2(\mathbf{r}_{ij})$, can be computed as the solution of an integral equation, and the solutions agree quite well with the experimental curves.

The knowledge of the complete set of functions ρ_n plus that of the intermolecular forces would permit the computation of all equilibrium properties of the liquid, and indeed if the intermolecular forces are the sum of pair forces, only a knowledge of ρ_2 at all P, T values is necessary. An adequate, although numerically difficult, theory of the transport properties also exists, using the equilibrium functions, ρ_n . At present, only qualitative success is obtained in the completely *a priori* use of the equations.

Associated Liquids. The description given above is adequate only for liquids composed of spherically symmetric molecules or molecules that are nearly so. These constitute the so-called normal liquids, which obey reasonably well the law of corresponding states, for which the entropy of vaporization at the boiling point has the Trouton's Rule value of approximately 21 cal/deg. For molecules containing large dipole moments,

or those forming mutual hydrogen bonds, the concept of the probability density functions must be extended to include angles or other internal degrees of freedom in the coordinates. Such inclusion is conceptually easy, but incredibly complicates the already difficult numerical evaluation of any equations. However, certain qualitative statements may be made.

Liquids composed of molecules with large dipole moments are frequently referred to as associated. Although in some instances relatively stable dimer or definite polymer units of relatively fixed orientation may exist, in many cases, notably water, it is extremely doubtful if an exact knowledge of the structure would reveal any distinguishable entities of associated molecules other than that of the whole liquid. In such cases, one would, however, expect that certain mutual angular orientations between neighboring molecules will be highly preferred, whereas in the dilute gas this will not be the case. The effect of this restriction on the internal coordinates will be to decrease the entropy of the liquid markedly compared to the gas. This effect is qualitatively the same as in association, and the properties of these liquids, particularly the high entropy of vaporization, will simulate those of a liquid composed of definite associated complexes.

LUMINANCE

Light has been defined¹ as "the aspect of radiant energy of which a human observer is aware through the visual sensations which arise from the stimulation of the retina of the eye."

One can specify the *radiant intensity* of a point source in a given direction quite simply as so many ergs/second/steradian (cgs system), or as watts/steradian (mks system). Similarly one can specify the *radiance* of an extended source, i.e., the areal density of point sources of unit radiant intensity to which the extended source is equivalent, as so many ergs/second/steradian/square centimeter, or as watts/steradian/square meter.

The problem, however, is that the visual effect is not simply related to the amount of radiation expressed in physical terms. It is evident from observation of the spectrum of a source radiating equal amounts of energy per unit wavelength interval throughout the visible spectrum, that equal energy per unit wavelength interval does not produce visual sensations having equal brightness. The problem is further compounded by the fact that the visual effect is also dependent upon the size of the field viewed, the duration of stimulation to some extent, the part of the retina stimulated, the adaptation state, and the characteristics of the individual observer.

For given conditions of observation, however,

and a sufficiently large number of observers, one can determine the average *relative luminous efficiency* of a monochromatic radiation, i.e., the ratio of the luminous efficiency of that radiation to the maximum luminous efficiency, by a variety of indirect methods. The work of Gibson and Tyndall² is particularly relevant here as being the basis for the standards adopted by the International Commission on Illumination at Geneva in 1924.

Luminous flux can now be defined as "*that quantity characteristic of radiant flux which expresses its capacity to produce visual sensation, evaluated according to the values of relative luminous efficiency adopted by the International Commission.*"¹ The luminous equivalent of radiant intensity and radiance now become *luminous intensity* and *luminance*. The former is defined, in any direction, as *the ratio of the luminous flux emitted by a source or by an element of a source, in an infinitesimal cone containing this direction, to the solid angle of this cone.*³ The latter is defined, at a point of a surface and in any direction, as *the ratio of the luminous intensity in that direction of an infinitesimal element of the surface containing the point under consideration, to the orthogonally projected area of this element on a plane perpendicular to that direction.*⁴

The unit of luminous intensity is the *candela*, which is of such a value that the luminous intensity of a full radiator at the freezing point of platinum is 60 units of luminous intensity per square centimeter. The unit of luminous flux is the *lumen*, the flux emitted in a solid angle of one steradian by a uniform point source having an intensity of one candela.

Since luminance is expressed in terms of luminous intensity per unit projected area, the unit of luminance is the candela per unit area. The unit recognized internationally is the *nit*, the candela per square meter. The other unit in the metric system is the *stilb*, or candela per square centimeter. In the British system, the units used are the candela per square inch and the candela per square foot.

Luminance can also be assessed in terms of reflected or emitted luminous flux per unit area, and this is the rationale for the system of units based on the lumen per unit area. The primary unit in the metric system is the *lambert*, the unit of a perfectly diffusing surface, emitting or reflecting light at the rate of one lumen per square centimeter. Commonly used derivatives of the lambert are the *millilambert* (10^{-3} lambert), and the *microlambert* (10^{-6} lambert). Sometimes encountered is the *apostilb* (10^{-4} lambert), which is the luminance of an ideal diffuser emitting or reflecting one lumen per square meter. The *foot-lambert* is the luminance of an ideal diffuser emitting or reflecting one lumen per square foot.

Since an ideal diffuser with a luminance of one candela per unit area in all directions, emits π (3.1416) lumens per unit area, one candela per square centimeter will be equal to π lamberts; one candela per square foot will be equal to π foot-lamberts; and one nit will be equal to π apostilbs.

This multiplicity of units is unfortunate, but should not be confusing if the above relationships are remembered. The obvious solution is to use the most convenient system and convert when necessary. Table I should prove helpful.

LUMINESCENCE

Introduction. Luminescence is the phenomenon of light emission in excess of thermal radiation. Excitation of the luminescent substance is prerequisite to the luminescent emission. Photoluminescence depends upon excitation by photons; cathodoluminescence, by cathode rays; electroluminescence, by an applied voltage; chemiluminescence, by utilization of the energy of a chemical reaction. Luminescent emission involves optical transitions between electronic states characteristic of the radiating substance. The phenomenon is essentially the emission spectroscopy of gases, liquids, and solids. The same basic processes may yield infrared or ultraviolet radiation in substances with suitable electronic energy states; therefore, such emission in excess of thermal radiation is also described as luminescence.

Luminescence can be distinguished from the Raman effect, Compton and Raleigh scattering and Cherenkov emission on the basis of the time delay between excitation and luminescent emission being long compared to the period of the radiation, λ/c , where λ is the wavelength and c is the velocity of light. The radiative lifetimes of the excited states vary from 10^{-10} to 10^{-1} second depending on the identity of the luminescent substances whereas λ/c is approximately 10^{-14} second for visible radiation. At ordinary densities of excitation, the spontaneous transition probability predominates so that the luminescent radiation is incoherent; under conditions of high densities of excitation in suitable luminescent substances, the induced transition probability may predominate, the emitted radiation is coherent, and laser action is attained.

The initial persistence of luminescent emission following the removal of excitation depends on the lifetime of the excited state. This emission decays exponentially and is often called fluorescence. In many substances, there is an additional component to the afterglow which decays more slowly and with more complex kinetics. This is

called phosphorescence. For many inorganic crystals, the emission spectra for fluorescence and phosphorescence are the same; the difference in afterglow arises from electron traps from which thermal activation is prerequisite to emission. For organic molecules, the emission spectra for fluorescence and phosphorescence are often different: the former occurs from an excited singlet; the latter, from a triplet state.

Luminescence of Gases. The simplest luminescent substances are monoatomic gases. The electronic states are characteristic of the isolated atoms; therefore, the excitation and emission spectra depend only on the differences in energy of the stationary electronic states of the many-electron atom, and the spectral lines are broadened only by the lifetimes of the excited states or at higher pressures, by collisions. The transitions are to a good approximation one-electron transitions. Resonance fluorescence is photoluminescence in which the exciting radiation is the exact frequency or wavelength for the transition from the ground to the excited state and emission occurs with the same frequency. Resonance fluorescence is shown diagrammatically in Fig. 1 for low pressure alkali

FIG. 1. Resonance fluorescence of atoms, e.g., Na.

metal vapor. The well-known 2537Å line of mercury vapor is another example of resonance fluorescence. This emission can also be excited by electrons accelerated by 5 or more volts. The simplest case of sensitized fluorescence (photoluminescence in which absorption of the exciting radiation is by one substance and the excitation is transferred to another which emits radiation) occurs with mixtures of monoatomic gases. For example, the characteristic fluorescence of thallium is observed when mixtures of Tl and Hg vapors are illuminated with the 2537Å radiation of Hg.

For diatomic and polyatomic gases, the energies of the electronic states are dependent on the interatomic distances of the molecule. This dependence is shown in Fig. 2 for the ground and excited states. For a diatomic molecule the coordinate R is the distance between the two atoms. For each electronic state, there is a series of vibrational levels which are also shown in Fig. 2. Optical transitions occur between individual vibrational levels of one electronic state and individual vibrational levels of another electronic state. These transitions occur in accordance with the Franck-Condon principle, i.e., with fixed

FIG. 2. Configuration coordinate model.

nuclear coordinates, vertically as shown in transitions 1 and 2 of Fig. 2. In most cases the emission will involve a smaller transition energy and occur at longer wavelength than the photoexcitation. This is referred to as Stokes' emission. In some cases, for example at high temperatures when the higher vibrational levels of the ground electronic state are populated thermally, anti-Stokes' emission is also observed. Additional structure in the photoexcitation and emission spectra arises from rotational states of the molecule. Iodine is a typical diatomic luminescent molecule excited by green light with visible emission at slightly longer wavelengths. Benzene and aniline are typical polyatomic molecules which are luminescent as vapors.

Luminescence of Organic Materials. The electronic states of most organic luminescent materials in the liquid or solid phase, either as pure materials or as solutes in dilute concentration in inert solvents, are to a good approximation describable in terms of the electronic states of the free molecule in the gaseous phase. In other words, the intermolecular forces are weak compared to the intramolecular forces. The photoexcitation and luminescent emission spectra of these substances in condensed phases are similar to the spectra of the vapors. The intermolecular forces are, however, great enough to bring about broadening of absorption and emission lines and in some cases to bring about electronic energy transfer between molecules before intramolecular, vibrational relaxation with the accompanying Stokes' shift can occur. On the other hand, in a viscous or rigid medium collisional, non-radiative de-excitation is reduced.

Many of the organic luminescent materials are aromatic molecules related to dyes. The sodium salt of fluorescein in dilute aqueous solution is well known as an efficient fluorescent material. Other organic substances luminesce efficiently when dissolved in organic solvents. Terphenyl in xylene is a liquid β - and γ -ray scintillator with emission in

the near ultraviolet. Some organic molecules luminesce most efficiently in a rigid medium. A solid solution of 1 per cent anthracene in naphthalene is a scintillator with blue emission. For these solutions, energy is absorbed by the solvent molecules and transferred to the solute where the luminescent emission occurs. Crystals of some pure organic substances luminesce, particularly at low temperatures.

The fluorescent emission and the long-wavelength absorption of organic materials are often simply related as mirror images of each other. This is shown in Fig. 3 for rhodamine in ethanol

FIG. 3. Mirror symmetry of absorption and emission.

and can be explained on the basis of the configuration coordinate model in Fig. 2. with the force constants for the two electronic states approximately equal. For organic molecules, the configuration coordinate R is interpreted as representing, schematically, all the intramolecular nuclear coordinates. In addition to the fluorescent emission, many organic substances exhibit phosphorescent emission. This arises from non-radiative relaxation from the excited singlet to the triplet state followed by radiative decay from the triplet to the ground singlet state, as illustrated in Fig. 4. Because of the spin selection rule governing radiative transitions, the triplet has a long lifetime and the oscillator strength for direct excitation to the triplet is negligible. In suitable systems,

FIG. 4. Fluorescence and phosphorescence of organic molecules.

polarized excitation and emission arising from the anisotropy of the organic molecules can be observed.

Chelates involving organic molecules as ligands bound to a metal atom or ion are a class of substances with members which luminesce. The fluorescence and phosphorescence of chlorophyll both *in vivo* and *in vitro* have been investigated for many years. On the other hand, rare earth chelates with organic ligands have been intensively investigated quite recently as lasers. The photoexcitation occurs in the broad absorption bands of the ligand; the energy is transferred to the localized 4f shell of the rare earth by a mechanism related to the transfer process occurring in the scintillators; luminescent line emission characteristic of the rare earth occurs, as coherent radiation with high excitation intensities. More recently, a fluorinated Eu-acetate dissolved in acetonitrile has been announced as a liquid laser operating near room temperature.

Luminescence of Inorganic Crystals. Inorganic crystals which luminesce are often called phosphors. Their luminescence in most cases originates from impurities or imperfections. Exceptions include the luminescence of alkaline earth tungstates which is characteristic of the WO_4 group perturbed by the crystal field, the luminescence of some rare earth salts, and radiation recombination of conduction electrons with valence band holes in semi-conductors. The impurities and imperfections responsible for luminescence in inorganic crystals are of diverse atomic and molecular types whose characteristics depend on the structure of the defect and on the electronic structure of the pure crystal. In some cases, the electronic states involved in the luminescence can be described in terms of energy levels of the impurity ion perturbed by the crystal field; in other cases, in terms of the crystal band structure perturbed by the impurity. The existence of conduction bands in inorganic crystals, particularly in semiconducting crystals, introduces additional mechanisms for the excitation of luminescence and for phosphorescence. For example, suitable impurities can be excited by alternate capture of injected conduction electrons and valence band holes, thus providing one mechanism for electroluminescence; on the other hand, an excited luminescent impurity may lose an electron to another defect via the conduction band, and the thermal activation necessary for return to the luminescent impurity is responsible for phosphorescence.

The alkali halides are simple ionic crystals which become luminescent when doped with suitable impurities. Thallium substituted in dilute concentration at cation sites in potassium chloride has the absorption and emission shown in Fig. 5. The absorption bands involve the $^1S \rightarrow ^3P^0$, $^1P^0$ transitions of the free ion perturbed by crystal interactions; the principal emission band, $^3P^0 \rightarrow ^1S$, is similarly perturbed. The spectra can be understood qualitatively with the aid of Fig. 2, modified with a second excited state and with the configuration coordinate interpreted as symmetric

FIG. 5. Spectra of KCl:Tl.

displacement of the six nearest-neighbour Cl from the Tl^{+} . It is this interaction which is most dependent on the electronic state of the Tl^{+} and is, therefore, largely responsible for the band widths and Stokes' shift.

Many inorganic crystals become luminescent when certain transition metal ions are dissolved in them. The luminescence involves intercombination transitions within the $3d$ shell; therefore, crystal field theory can be used to interpret the absorption and emission spectra. Divalent manganese is a common activator ion. Zn_2SiO_4 , ZnS and $3Ca_3(PO_4)_2 \cdot CaF_2$ are important phosphors activated with Mn^{+2} . The last, activated also with Sb^{+3} , is the principal fluorescent lamp phosphor. The excitation at 2537\AA from the Hg discharge occurs at the Sb^{+3} , whose energy level structure is similar to that of Tl^{+} ; part of the energy is radiated in a blue band due to Sb^{+3} and part is transferred to the Mn^{+2} which is responsible for an orange emission band. The ruby laser involves the luminescence of Cr^{+3} in Al_2O_3 . Excitation occurs in a broad absorption band, the system relaxes to another excited state from which emission occurs in a narrow band.

Rare earth ions, particularly trivalent, in solid solution in inorganic crystals and in glasses exhibit the emission characteristic of transitions in the $4f$ shell. For examples, samarium, europium, and terbium give visible emission; neodymium, infrared; and gadolinium, ultraviolet. Because of their narrow emission bands, the rare earth activated phosphors are of interest as lasers and photon counters. Crystal field theory can be used to explain the optical absorption and luminescent emission of the $4f$ transitions of rare earth ions in crystals and glasses.

The zinc sulfide phosphors, which are widely used as cathodoluminescent phosphors and well-known for their electroluminescence, are now recognized as large band gap, compound semiconductors. Two impurities or imperfections are essential to the luminescence of many of these phosphors; an activator which determines the emission spectrum and a coactivator which is essential for the emission but in most cases has no effect on the spectrum. Activator atoms such as

Cu, Ag and Au substitute at Zn sites and perturb a series of electronic states upward from the valence band edge. In a neutral crystal containing only these activator impurities, the highest state is empty, i.e., it contains a positive hole and can accept an electron from the valence band; therefore, in semiconductor notation, the activator is an acceptor. In a similar way, coactivators such as Ga or In at Zn sites or Cl at S sites are donors. The simultaneous introduction of both types of impurities results in electron transfer from donor to acceptor lowering the energy of the crystal and leaving both impurities charged. The coulomb attraction of the donor and acceptor leads to a departure from a random distribution over lattice sites and to pairing. The electronic states and some of the transitions of acceptors, donors and donor-acceptor pairs are shown in Fig. 6. The spectrum of $ZnS:Cu, Ga$ is shown in Fig. 7. The longer-wavelength emission band involves the transition from the lowest donor state to highest acceptor state (transition 3) in approximately fifth nearest-neighbor pairs; the shorter-wavelength emission corresponds more nearly to transition 1 of Fig. 6. Luminescent emission from donor-acceptor pairs has been more clearly seen with gallium phosphide crystals. In addition to luminescence due to donors, acceptors and their pairs, emission bands due to transition metals are well known for zinc sulfide as noted earlier. In zinc sulfide crystals, the

FIG. 6. Band model for acceptor, donor, and pair transitions.

FIG. 7. Spectra of $ZnS: Cu, Ga$.

donors which are unassociated with acceptors serve as electron traps and are responsible for long-persistent, temperature-dependent phosphorescence.

M

MAGNETIC FIELD

Basic Equations. To separate electromagnetic theory from the theory of the solid state, Maxwell's equations can be written in terms of the magnetic induction or flux-density \mathbf{B} and the total current density \mathbf{J} :

$$\nabla \cdot \mathbf{B} = 0 \quad (1)$$

$$\nabla \times \mathbf{B} = 4\pi\mathbf{J} \quad (2)$$

where, for purposes of the present article, the displacement current $(1/c^2)\delta\mathbf{E}/\delta t$ is neglected relative to $4\pi\mathbf{J}$ (see ELECTROMAGNETIC THEORY and MAGNETISM).

The solution of Eqs. (1) and (2) is

$$\mathbf{B}(\mathbf{r}) = \int d^3r_1 \frac{\mathbf{J}(\mathbf{r}_1) \times (\mathbf{r} - \mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|^3} \quad (3)$$

where the integral includes all current-carriers, and \mathbf{B} vanishes at infinity. In terms of the vector potential \mathbf{A} ,

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (4)$$

and the gauge $\nabla \cdot \mathbf{A} = 0$, one has

$$\nabla^2 \mathbf{A} = -4\pi\mathbf{J} \quad (5)$$

and

$$\mathbf{A}(\mathbf{r}) = \int d^3r_1 \frac{\mathbf{J}(\mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|} \quad (6)$$

for \mathbf{A} vanishing at infinity.

Magnetic lines of force are defined by $d\mathbf{r} \propto \mathbf{B}$ and are endless, by virtue of Eq. (1). The magnetic flux Φ through a surface S , bounded by a closed curve ℓ , is given by

$$\Phi = \int dS \mathbf{B} \cdot \mathbf{n} = \oint d\ell \cdot \mathbf{A} \quad (7)$$

where \mathbf{n} is the normal to S . The flux tube defined by the field lines passing through ℓ contains constant flux, independent of S .

At a large distance from a localized current distribution at $\mathbf{r} = 0$, Eq. (6) gives the dipole potential

$$\mathbf{A} = \frac{\mathbf{m} \times \mathbf{r}}{r^3} \quad (8)$$

where

$$\mathbf{m} = \frac{1}{2} \int d^3r_1 \mathbf{r}_1 \times \mathbf{J}(\mathbf{r}_1) \quad (9)$$

Equations in the Presence of Magnetic Materials. A macroscopic current density \mathbf{J}_M can be defined by local averaging of the microscopic current density \mathbf{J}_m within magnetic materials

$$\mathbf{J}_M = \langle \mathbf{J}_m \rangle_{av} \quad (10)$$

More conveniently, a magnetization vector \mathbf{M} can be introduced, where

$$\mathbf{J}_M = \nabla \times \mathbf{M} \quad (11)$$

In experiments, only \mathbf{J}_M can be measured directly (via measurements on \mathbf{B}), and \mathbf{M} is then uniquely derivable from Eq. (11) only with the added condition that it is to be a local state variable of the magnetic material (i.e., it is constant in uniform samples and constant fields). This condition follows automatically from the interpretation of \mathbf{M} as a magnetic-moment density per unit volume:

$$\mathbf{M} = N\mathbf{m}_0 \quad (12)$$

The theoretical molecular magnetic moment \mathbf{m}_0 (with number density N) is derived from \mathbf{J}_m by evaluation of Eq. (9) over the molecular volume.

For macroscopic purposes, the total current density \mathbf{J} of the preceding section is now specified by

$$\mathbf{J} = \mathbf{J}_c + \mathbf{J}_M \quad (13)$$

The component \mathbf{J}_c flows in conductors of resistivity η in accordance with Ohm's Law:

$$\eta \mathbf{J}_c = \mathbf{E} \quad (14)$$

The component \mathbf{J}_M is derived from \mathbf{M} .

In the analysis of configurations involving magnetic materials, the magnetic field \mathbf{H} is a convenient vector

$$\mathbf{H} = \mathbf{B} - 4\pi\mathbf{M} \quad (15)$$

Then Eqs. (1) and (2) take the form

$$\nabla \cdot \mathbf{H} = -4\pi \nabla \cdot \mathbf{M} \quad (16)$$

$$\nabla \times \mathbf{H} = 4\pi \mathbf{J}_c \quad (17)$$

At the interface between two magnetic materials, Eqs. (1) and (17) imply continuity of the normal component of \mathbf{B} and of the tangential component of \mathbf{H} .

Across a sheet-current of density I_c/ℓ per unit length, the tangential component transverse to

\mathbf{J}_c of both \mathbf{H} and \mathbf{B} undergoes an increment $4\pi I_c/l$. The other components of \mathbf{H} and \mathbf{B} are unaffected.

For weakly magnetic materials, Eq. (15) can generally be written in terms of a scalar magnetic permeability μ

$$\mu \mathbf{H} = \mathbf{B} \quad (18)$$

For ferromagnetic materials, one can still write

$$\mu \mathbf{H} = \mathbf{B} - 4\pi \mathbf{M}_0 \quad (19)$$

where \mathbf{M}_0 is a permanent magnetization, but μ now depends on the time history as well as the magnitude of \mathbf{H} .

When \mathbf{J}_c is zero everywhere, one can define a scalar potential Ω , such that

$$\mathbf{H} = -\nabla \Omega \quad (20)$$

$$\nabla^2 \Omega = 4\pi \nabla \cdot \mathbf{M} \quad (21)$$

If the boundary condition on Ω is simply that it vanish at infinity, the solution is

$$\Omega(\mathbf{r}) = -\int d^3 r_1 \frac{\nabla_1 \cdot \mathbf{M}(\mathbf{r}_1)}{|\mathbf{r} - \mathbf{r}_1|} \quad (22)$$

In the presence of current-carrying conductors Eqs. (20) and (21) still hold in the region where $\mathbf{J}_c = 0$, but Eq. (17) now implies a multivalued potential

$$\oint d\mathbf{l} \cdot \mathbf{H} = \oint d\Omega = 4\pi I_c \quad (23)$$

where the integral is taken around a loop enclosing the total conductor current I_c . To keep the potential single-valued, so that the solution of Eq. (22) remains valid, one may adopt the "magnetic-shell" approach: \mathbf{J}_c is replaced with an equivalent \mathbf{M} , in analogy with Eq. (11).

Magnetic Force and Energy. From Maxwell's stress tensor, we find the volume force

$$\mathbf{f} = -\nabla \left(\frac{B^2}{8\pi} \right) + \frac{1}{4\pi} (\mathbf{B} \cdot \nabla) \mathbf{B} \quad (24)$$

$$= \mathbf{J} \times \mathbf{B}$$

which agrees with the summation of the Lorentz forces on the moving charges composing \mathbf{J} . The "magnetic pressure" against a current sheet bounding a region of finite \mathbf{B} (as in the Meissner effect or ordinary skin effect) is thus $B^2/8\pi$, evaluated at the surface. The force and torque on a body localized in a nearly uniform field are

$$\mathbf{F} = (\mathbf{m} \cdot \nabla) \mathbf{B} \quad (26)$$

$$\mathbf{N} = \mathbf{m} \times \mathbf{B} \quad (27)$$

From the microscopic point of view underlying Eq. (2), the magnetic energy density is

$$w = \frac{B^2}{8\pi} \quad (28)$$

In the presence of magnetic materials, one is more interested in the electrical input energy

required to go from \mathbf{B}_0 to \mathbf{B} , and this is given by

$$\Delta w = \frac{1}{4\pi} \int_{\mathbf{B}_0}^{\mathbf{B}} \mathbf{H} \cdot d\mathbf{B} \quad (29)$$

For $\mathbf{H} = \mu \mathbf{B}$, with constant μ , this becomes

$$\Delta w = \frac{1}{8\pi\mu} (B^2 - B_0^2) \quad (30)$$

The derivation of Eqs. (28) and (29) depends on the complete set of Maxwell's equations.

MAGNETIC RESONANCE

Electrons revolve about the nucleus of an atom and spin around their axes; in addition, the nucleus has a spin of its own. All of these moving charges have associated magnetic fields (magnetic moments), and *magnetic resonance* is concerned with the interactions of some of these fields with each other and with at least two external magnetic fields applied to the atom.

To facilitate understanding, consider an electron circulating about the nucleus. The electron has angular motion and it is a charged particle held in orbit by the oppositely charged

nucleus. Assume KEPLER'S LAW of areas applies (radius vector of the particle sweeps out equal areas in equal times) and that angular momentum, P_ϕ , is conserved and quantized ($P_\phi = L\hbar = mr^2\dot{\phi}$); $L \equiv$ orbital quantum number, and $\hbar \equiv$ Planck's constant/ 2π . The area swept out in one period, t , is:

$$A = \int_0^t \frac{1}{2} (r^2 \dot{\phi}) dt = L\hbar t / 2m.$$

From Amperes Law, one can find the equivalent magnetic dipole moment, μ , produced by a closed current loop, I , to be: $\mu = I \cdot A$. Since current is e/t it follows that

$$\mu = L(e\hbar/2m) \quad (1)$$

and $e\hbar/2m$ is defined as a Bohr magneton, μ_B .

Next, consider the ELECTRON SPIN about its own axis. A classical derivation of the spin moment similar to the above produces an electron spin

moment of two Bohr magnetons. Dirac's relativistic quantum theory of the electron and many experiments give the correct value of one Bohr magneton; this means the spin quantum number of the electron is $1/2$.

The total angular momentum, P_J , is found by adding vectorially the orbital and spin angular momentum of the electron, $P_J = P_L + P_S = \hbar(L + S)$ and the total magnetic moment becomes: $\mu = \mu_B(L + 2S)$. P_L and P_S can be thought of as precessing about P_J and only their components in the direction of P_J contribute to the average magnetic moment. Vectorially adding the moments gives:

$$\begin{aligned}\mu_J &= \mu_B [L \cos(LJ) + 2S \cos(SJ)] \\ &= \mu_B J \left(1 + \frac{S^2 + J^2 - L^2}{2J^2} \right)\end{aligned}$$

or using a more rigorous wave mechanics approach S^2 is replaced by $S(S + 1)$, etc., to give:

$$\mu_J = \mu_B gJ \quad (2)$$

where

$$g \equiv 1 + \frac{S(S + 1) + J(J + 1) - L(L + 1)}{2J(J + 1)}$$

The quantity g is called the Landé g -factor and for an atom in the ground state $L = 0$, $S = J$, and g becomes equal to 2. We could add the nuclear spin and its magnetic moment to this and the vector problem would become complex indeed! This will be done later in an easier way.

For simplicity, we will now add the external magnetic field, H . Just as a spinning top will precess in the earth's gravitational field, so will the magnetic moment vector of the electron precess in the magnetic field, the torque in the electron case being produced by the interactions of the dipole and the external field. Equating the time rate of change of angular momentum to the torque on the dipole, one can derive the precessional frequency in complete analogy to the top problem.

This precessional frequency, called the Larmor frequency, can also be derived from an energy standpoint and will give us more insight. The potential energy of a magnetic dipole in a magnetic field is $W = -\mu H = \mu_B g J H$. If we confine ourselves to an atom in the ground state then $J = S$ and $S = \pm 1/2$, the spin being either parallel or antiparallel with the external field. The magnetic moment is defined as positive or negative according to the condition of parallelism or antiparallelism, respectively.

Thus the energy difference between the two possible electron spin states can be equated to $\hbar\omega_L$, where ω_L is the Larmor frequency of precession.

$$\hbar\omega_L = W(S = \frac{1}{2}) - W(S = -\frac{1}{2}) = g\mu_B H = \gamma H \quad (3)$$

Electromagnetic radiation at the Larmor frequency and with the correct polarization will be absorbed by dipoles in the lower state, making

transitions to the higher state. This is shown in Fig. 1(b). *Electron spin resonance* is the technique for measuring this splitting using radio-frequency technology.

Since the nucleus is known to carry a charge, its angular spin should and does produce a nuclear magnetic moment. A nuclear magneton, μ_n , is defined in the same manner as the Bohr magneton, except the mass of the electron is replaced by the mass of the proton. A nuclear g -factor ($g_n \equiv gI$) is also defined where I is the spin of the nucleus.

The proton's magnetic moment is 2.7935 nuclear magnetons while the neutron's moment is $-1.9135 \mu_n$. The positive or negative sign refers to the condition of whether the angular momentum vector has the same or opposite direction as the magnetic moment. A nucleus with a spin, I , will have $2I + 1$ possible orientations in a magnetic field and corresponding $2I + 1$ energy levels. These give rise to a hyperfine structure.

For simplicity, consider a hydrogen atom in a molecule. The nucleus is a proton with a spin of $1/2$ and, consequently, its magnetic moment is either parallel or antiparallel to the field. This produces energy levels as shown in Fig. 1(c).

FIG. 1. Magnetic resonance energy levels. (a) orbital electron energy level; (b) electron spin moment in a magnetic field; (c) nuclear spin magnetic moments in a magnetic field.

Nuclear magnetic resonance is concerned with the use of radio-frequency techniques to study the transitions between nuclear spin states; in the case shown $\hbar\omega = g_n \mu_n H$ for the transition.

Consider a system of free magnetic dipoles in an external magnetic field. The magnetic dipoles would seek a position of minimum potential energy and consequently turn parallel with the field. In the world of nuclei and atoms we do not have such a closed system. The thermal agitation of the molecules and atoms coupled to the nuclear spin through magnetic and electric field interactions produces a disorienting effect which tends to fill all energy states equally.

The energy for each degree of freedom of a molecule is $(\frac{1}{2})kT$ and at room temperatures is roughly 10^{-14} ergs while the difference in energy between the two states of a proton (hydrogen nucleus) in a magnetic field of 10,000 oersteds is about 10^{-20} ergs ($W = g\mu_n H$).

For some solids and for liquids near absolute zero, more sophisticated distributions must be used, but for liquids and gasses at room temperature, a simple Boltzmann distribution will be adequate, $N \propto e^{-E/kT}$. Thus, the ratio of the populations of the two states used for an example would be $N(\frac{1}{2})/N(-\frac{1}{2}) \approx e^{(g\mu_n H/kT)}$ and for these protons at room temperature, one would find about seven more in the lower energy state out of every million.

As in electron resonance experiments, when an rf field is applied to the sample at right angles to the external field, an in-phase component of the rf field will cause the protons in the lower energy state to "flip" into the higher and the protons in the higher energy state into the lower.

In practice only, a certain percentage of each population is "flopped." However, a simple calculation will show that the population in both states will soon be practically the same; this condition is called saturation. The spin-lattice relaxation time, T_1 , is defined as the time during which all but $1/e$ of the excess spins will have reached the final equilibrium state of lowest energy.

Let A_0 be the magnitude of the energy absorbed to reach saturation; then A_0 is proportional to $g\mu_n H/kT_0$ where T_0 is the absolute temperature of the sample. If resonance absorption is permitted to take place before equilibrium of the excess occurs, then the energy absorbed is defined by a new T . This leads to the concept that resonance elevates the spin temperature, or heats up the spins; and after resonance stops, the spins cool to the temperature of the lattice. The lattice is defined as everything in the sample but the spin in question. T_1 for nuclear moments varies from hours to milliseconds, and for oxygen-free water at room temperature, it is about 3.6 seconds.

Another relaxation effect is that associated with the spin-spin interaction. Imagine an effective inhomogeneity in the external field of magnitude ΔH to exist over the region of a sample of the nuclear moments being studied. There will be variations in the external field at different nuclei, and we obtain in effect a spread in the Larmor frequencies throughout the sample, $|\Delta\omega| \approx |\gamma| |\Delta H|$. Spin-spin interactions are concerned with the effect of each precessing moment on the neighboring spins through their magnetic fields. Thus, the total field at each nucleus consists of the external field value and the resultant of the local fields produced by the components of the neighboring magnetic dipoles. T_2^* (transverse, spin-spin, or phase relaxation time) is defined as the time characteristic of the spread in Larmor frequencies. T_2 is the time during which all but $(1/e)$ of a system of spins whose phase has been established return to a state of random phase.

If the external field is quite homogeneous, the fields produced by neighboring dipoles are sufficient to actually separate the resonance absorption spectra of the molecule into patterns which identify the molecule. A very simple example of this is shown in Fig. 2 where the magnetic resonance spectra of ethyl alcohol is shown. In

FIG. 2. Nuclear magnetic spectra of ethyl alcohol. Experimentally, the rf radiation on the atoms is usually held constant while the external magnetic field is varied. Absorption takes place when the Larmor frequency coincides with the radio frequency.

each of the three peaks, the proton of the hydrogen atoms is causing the resonance absorption.

A little thought and the use of symmetry arguments will show that the largest peak belongs to CH_3 , the next largest to CH_2 , and the smallest absorption to OH . Nuclear magnetic resonance (NMR) has become a very powerful tool for organic chemists. Magnetic resonance is also used to study free radicals, crystalline orientation, and many other things concerning the structure of matter.

MAGNETISM

Magnetization. Magnetic fields are produced both by macroscopic electric currents and by magnetized bodies. The first observed manifestations of magnetism were the forces between naturally occurring permanent magnets, and between these and the earth's field. North- and south-seeking poles could be identified. Poles were observed to be localized near the ends of long rods magnetized by contact with natural magnets or by a current-carrying coil. From the observed attraction and repulsion of unlike and like poles with an inverse square law came the concept of pole strength and the definition of the unit pole, that which acts on another in vacuum with a force of one dyne at a distance of one centimeter. The unit magnetic field, the oersted, could then be defined as that in which a unit pole experiences a force of one dyne. The magnetic moment of a long, uniformly magnetized rod of length l with a pole strength of m unit poles at each end is defined as ml , the largest couple that the sample can experience in a field of one oersted. The magnetization, M , is defined as the magnetic moment per unit volume, ml/al , where a is the cross-sectional area, and is thus also equal to the pole strength per unit area, m/a .

Magnetic Induction. The induction, or flux density, B , is numerically equal to the field H in free space and is described as one line of flux per square centimeter for a field of one oersted. Its direction is that of the force on a unit north pole.

If magnetic material is present, the flux density is equal to $H + 4\pi M$, since 4π lines of force emanate from the unit pole at each end of a specimen of unit magnetization. Magnetic poles are observed to occur in pairs. Lines of B are continuous, i.e., $\text{div } B = 0$. If a material becomes strongly magnetized in a small field, the lines of flux can be considered to crowd into the material, leaving their original locations and reducing the field there. This is how magnetic shielding is accomplished. Changes of B within a coil induce voltages which can be measured and form the basis of galvanometer and fluxmeter measurement methods. For a coil of N turns of cross-sectional area a , in which the flux is changing at dB/dt gauss/sec, E in volts is given by

$$E = 10^{-8} Na \frac{dB}{dt}$$

Forces on magnetic bodies in field gradients are proportional to M .

Types of Magnetic Behavior. In general a field H will produce a magnetization M in any material. If M is in the same direction as H , a sample will be attracted to regions of stronger field in a field gradient. It will be repelled if M is in the opposite sense. This experiment, as first performed by Faraday, is the basis for the broad classification of materials into paramagnetic, diamagnetic, and ferromagnetic. The susceptibility κ is defined as M/H . The force F_z on a small specimen of volume v in a field H_y and a field gradient dH_y/dx is

$$F_z = (\kappa_2 - \kappa_1)vH_y \frac{dH_y}{dx}$$

where κ_1 and κ_2 are the volume susceptibilities of the specimen and the surrounding medium, usually air.

For paramagnetic materials, κ is small and positive, usually between 1 and 1.001 at ordinary temperatures. These substances contain atoms or ions with at least one incomplete electron shell, giving them a non-zero atomic or ionic magnetic moment μ_a . Many salts of the iron-group and rare-earth metals are paramagnetic, as are the alkali metals, the platinum and palladium metals, carbon, oxygen, and various other elements. Antiferromagnetic substances also have small positive κ , as do ferromagnetics above their Curie temperatures. In the classical theory of paramagnetism, the orientations of the moments are considered to be initially thermally randomized in space. An applied field produces a net magnetic moment in its direction, as described by the classical Langevin function

$$\frac{M}{M_s} = \coth\left(\frac{\mu_a H}{kT}\right) - \frac{kT}{\mu_a H}$$

where k is the Boltzmann constant. M_s is the value of M attained for very large H/T . Under most conditions, only the initial portion of this curve is observed, with the corresponding constant κ . The conduction electrons at the top

of the Fermi distribution in a metal can also give rise to a temperature-independent Pauli paramagnetism. The quantum-mechanical analogue of the Langevin function is called the Brillouin function (see PARAMAGNETISM).

For diamagnetic materials, κ is small and negative. Diamagnetism is a universal phenomenon but is often masked by paramagnetic or ferromagnetic effects. Net diamagnetic behavior is observed in a number of salts and metals, and in the rare gases, in which there is no net moment. The effect can be regarded as the operation of Lenz's law on an atomic scale (see DIAMAGNETISM).

Ferromagnetic materials show a value of M which may be of the order of 10^3 in small fields. Thus κ can be very large. It is common to describe their properties in terms of the permeability $\mu = B/H$. Since M saturates in ordinary fields, κ and μ are not constant. M is not necessarily in the same direction as H , so κ and μ are, in general, tensors. Furthermore, ferromagnetics generally exhibit hysteresis in the dependence of M on H , and the details are very structure-sensitive. Still another distinction is the rather abrupt disappearance of ferromagnetism at a characteristic temperature, the Curie temperature, T_c .

Atomic Magnetic Moments. There are two possible sources for the moments of individual atoms. They are electron orbital motion and electron spin (see ATOMIC STRUCTURE). In ferromagnetic materials, most of the moment comes from spin rather than orbital motion, a fact that is revealed experimentally by gyromagnetic measurements (see FERROMAGNETISM) and by magnetic resonance experiments (see MAGNETIC RESONANCE). The unit of atomic moment is the Bohr magneton, μ_B , which is the moment associated with one electron spin, numerically equal to 0.9274×10^{-20} erg/oersted. The spin quantum number, S , is one-half the number of unpaired electrons. The moment per atom is $g\mu_B S$, where g is the gyromagnetic ratio, close to 2 for most materials. The moment in Bohr magnetons of an isolated atom or ion of the first transition series is equal to the number of unpaired d electrons, considering the first five electron spins to have one orientation and the next five the opposite (Hund's rule). The Ni^{++} ion, with eight d electrons, has the expected moment of $2\mu_B$ in ferrites, in which the ionic spacing is great enough so that the d levels are not disturbed (see FERRITES). In metallic nickel, however, the d levels overlap considerably, and the moment corresponds to only $0.6\mu_B$ per atom. Similarly the Bohr magneton numbers for metallic iron and cobalt are 2.2 and 1.7 respectively.

Ferromagnetism. Ferromagnetism can only occur in a material containing atoms with net moments. Also, quantum-mechanical electrostatic "exchange" forces must be present, holding neighboring atomic moments parallel below the Curie temperature. These are much greater than the Lorentz force due to the average magnetization and are, in fact, equivalent to an effective field on the order of 10^6 oersteds. Such an effective "molecular field" was postulated in 1907 by

Weiss in extending the Langevin theory of paramagnetism to include ferromagnetic behavior. The Langevin function predicts a temperature dependence of magnetization, for small M , of

$$M = \frac{CH}{T}$$

where C is a constant. The susceptibility is then C/T , which is Curie's law. Weiss pointed out that if the field H were augmented by an additional field NM proportional to the magnetization, the temperature dependence became

$$M = \frac{CH}{T - T_c}$$

where $T_c = NC$. This is the Curie-Weiss law, approximately obeyed by ferromagnetic substances above their Curie points. Below T_c , the presence of the molecular field produces an alignment of the atomic moments corresponding to the spontaneous magnetization M_s even when no external field is present. However, ferromagnetic materials can have any value of magnetization, including zero, which seems to contradict this result. Weiss therefore postulated the existence of domains separated by boundaries. In each domain the atomic moments are parallel, the domain magnetizations having different orientations. The net external magnetization is then the vector sum of the domain magnetizations and can be varied by a rearrangement of the domain structure, which may happen in very small applied fields. This prediction has been completely verified by experiment. The motion of domain boundaries as observed under the microscope has been directly correlated with external changes in magnetization. Domain boundaries in iron are on the order of 1000 Angstroms thick. Within a boundary, neighboring magnetic moments are not quite parallel. The change in orientation of the magnetization from one domain to another is distributed through the thickness of the boundary.

Within a domain, the magnetization will in general preferentially lie along some particular crystallographic direction. The energy difference between magnetization in the easiest and hardest direction may approach 10^7 ergs/cm³. This anisotropy is described in an appropriate trigonometric series with coefficients K_i . Usually only a few terms are necessary. Often a material is described by a single K ; this implies a uniaxial anisotropy energy of the form $K \sin^2\theta$. The K_i may pass through zero and change sign with changing composition or temperature. Although such details cannot in general be predicted, the magnetocrystalline anisotropy will have the same over-all symmetry as the crystal structure. Anisotropy is best investigated in single crystals, by analysis of magnetization curves in various directions or from the relationship between the measured torque and the direction of the applied field (see FERROMAGNETISM). Dimensional changes are also associated with the position of the magnetization vector relative to the lattice (see MAGNETOSTRICTION).

There are two mechanisms available for changing the externally measured magnetization of a ferromagnetic material: domain boundary motion, and domain magnetization rotation. Broadly speaking, in magnetically soft materials, boundary motion accounts for most of the changes in low applied fields, leaving the magnetization in each domain in the easy direction nearest the applied field. Then rotation against anisotropy produces the remaining change in higher fields. In very low fields, boundary motion is practically reversible, but when boundaries move considerable distances, they experience a net drag from impurities and irregularities in the material, causing hysteresis in the dependence of B on H . There will in general be a remanence B_r , the flux density remaining after saturation when the field is reduced to zero, and a coercive force H_c , the reverse field required to reduce the flux density to zero. A loss associated with the irreversibility of magnetization changes also occurs in rotating fields. This loss becomes zero in very large fields, except in a few special cases.

Even in very slowly changing fields, a wall characteristically moves in jumps, each giving a sudden change in B . This irregularity has been known for a long time as the Barkhausen effect, and its physical origin is the irregularity of wall motion through various inhomogeneities in the material. Usually a very large number of these small jumps takes place. In special circumstances, however, the material may remain at B_r until, in a sufficiently large field, a single wall will be nucleated and sweep all the way across the specimen, leaving it at B_r in the other direction. Such a material has only two stable states, $+B_r$ and $-B_r$, a useful behavior in some applications.

It is also necessary to consider the behavior in rapidly varying fields, discussed below.

Antiferromagnetism. Exchange forces can operate to hold neighboring moments anti-parallel, rather than parallel. Materials whose magnetic moments are arranged in this way show no external permanent moment and are called antiferromagnetic. The sign of the exchange force may depend, among other things, on the atomic spacing. Metallic manganese, for example, is antiferromagnetic, while many alloys of manganese, in which the average Mn-Mn distance is greater, are ferromagnetic. In some antiferromagnetic compounds, the exchange interaction appears to be of a next-nearest-neighbor type, taking place through an intervening atom such as oxygen. This type of interaction is termed superexchange. Antiferromagnetic materials, having no net external moment, show small positive susceptibilities that reach a maximum at the temperature above which the exchange forces can no longer hold the moments aligned against thermal agitation. This temperature, T_N , the Néel temperature, corresponds to the Curie temperature of a ferromagnet. Magnetocrystalline anisotropy exists for antiferromagnets just as for ferromagnets (see ANTIFERROMAGNETISM).

Ferrimagnetism. With more than one type of magnetic ion present, in certain compounds,

antiferromagnetic coupling may lead to a net external moment corresponding to a Bohr magneton number equal to the difference in ionic moments. Other more complicated cases occur. Ferrites, insulating oxides with the spinel structure, are important examples of this class of material, called ferrimagnetics (see FERRIMAGNETISM).

Exchange Anisotropy. A ferromagnetic phase may be in exchange coupling with an antiferromagnetic phase, as in a cobalt particle covered with CoO. This leads to new phenomena, including non-vanishing high-field rotational hysteresis. Such a material cooled in a field through the Néel temperature, if $T_c > T_N$, may exhibit a hysteresis loop that is permanently displaced from the origin. This is equivalent to a unidirectional (not uniaxial) anisotropy and will appear in a torque curve as a $\sin \theta$ term. Ferromagnetic and antiferromagnetic regions in a single-phase alloy may also lead to these effects.

Other Configurations. Atomic moments need not necessarily be either parallel or antiparallel. In a few materials they may be arranged in a triangular or spiral configurations. In some circumstances, an antiferromagnetic material may shift to a configuration having a large ferromagnetic moment in the appropriate combination of fields and temperatures (metamagnetism).

Permanent Magnets. A useful permanent magnet material should have as large a hysteresis loop as possible. In the early magnet steels, wall motion was made difficult by a heterogeneous alloy structure. A different approach is based on the theory that sufficiently small particles should find it energetically unfavorable to contain domain boundaries. The critical size is proportional to $K^{1/2}/M_s$. Reversal must then proceed by the difficult process of rotation against shape, strain-magnetostriction, or crystal anisotropy. Fine-particle ($\sim 1000\text{\AA}$) iron and iron-cobalt materials utilizing shape anisotropy have been developed. A magnetic oxide, $\text{BaO} \cdot 6\text{Fe}_2\text{O}_3$, utilizes magnetocrystalline anisotropy in fine-particle ($\sim 1\mu$) form. The Alnico permanent magnet alloys have very fine precipitate structures and are probably also best regarded as fine-particle materials.

Thin Films. Since a surface atom's surroundings are different from those in the interior, the magnetization and Curie temperature of thin films should yield important information about the range of ferromagnetic interactions. Experimental difficulties, primarily with purity, have beclouded the subject to some extent, but it now appears that any surface layer on nickel having substantially different magnetic properties from the bulk cannot be more than a few Angstroms thick.

There have been many investigations of flux reversal in films, usually vapor-deposited on glass, which have been motivated by computer technology needs. Such films show a uniaxial anisotropy associated with fields present during deposition or sometimes with geometric effects such as the angle of incidence of the vapor beam.

Dynamic Behavior of Ferromagnetic Materials. Changes in flux in a conductor induce emf's resulting in current flows whose fields tend to oppose the change in flux. For various time rates and geometries these can be calculated, leading to expressions for phase relationships and skin depth in conductors (see ELECTROMAGNETIC THEORY). These expressions have often been applied to magnetic materials at power frequencies by simply replacing H by B . This is in general not a good approximation and leads to erroneous results. It is more nearly correct to recognize that highly localized eddy currents around moving domain boundaries are the entire source of loss under these conditions. For a given dB/dt , the loss calculated in this way is much greater, decreasing to the classical value as the density of domain boundaries increases.

In bulk metals, domain wall velocities are usually determined by the damping associated with local eddy currents. In ferrites and thin films, other types of damping may predominate. These and many other aspects of the dynamic behavior of magnetic materials of all types have been investigated through resonance methods (see MAGNETIC RESONANCE).

Superparamagnetism. For particles whose volume v is on the order of 10^{-18} cm^3 or less, the direction of the entire particle moment $M_s v$ may fluctuate thermally. An assembly of such particles will exhibit the Langevin function magnetization curve of a paramagnetic with the extremely large moment $M_s v$; thus it may be easily saturated with ordinary fields and temperatures. Such magnetization curves can be used to study particle sizes and size distributions.

MAGNETO-FLUID-MECHANICS

Magneto-fluid-mechanics is the subject that deals with the mechanics of electrically conducting fluids (such as ionized gases and liquid metals) in the presence of electric and magnetic fields.

Magneto-hydrodynamics is another name used extensively, but it suffers from the less general meaning of the words "hydro" and "dynamics." Other names used are: magneto-hydro-mechanics, magneto-gas-dynamics, magneto-plasma-dynamics, etc.

The fundamental assumptions underlying magneto-fluid-mechanics are those of continuous media. In this respect, magneto-fluid-mechanics is related to plasma physics (see PLASMAS) in the same way that ordinary fluid mechanics is related to the kinetic theory of gases. More specifically, such phenomenological coefficients as viscosity, thermal, and electrical conductivities, mass diffusivities, dielectric constant, etc., are assumed to be known functions of the thermodynamic state, as derived from microscopic considerations or experiments.

From electromagnetic theory, we know that the "Maxwell stresses" give rise to a body force made up of the following components: electrostatic (applied on a free electric space charge); ponderomotive (the macroscopic summation of the elementary Lorentz forces applied on charged particles); electrostrictive (present when the dielectric constant is a function of mass density); a force due to an inhomogeneous electric field and its magnetic counterpart; and the magnetostrictive force. For any fluid the last two forces are negligibly small at normal temperatures, whereas the ones associated with the behavior of the dielectric constant, although normally small, are of the same order of magnitude as the buoyant forces under certain conditions. On the assumption that we deal with electrically neutral but ionized fluids, the only substantial force that remains is the ponderomotive force. Indeed, what is today called magneto-fluid-mechanics deals almost exclusively with this force.

Fundamental Equations. The equations that govern magneto-fluid-mechanics are the following:

(1) Equation of conservation of mass, which is the same as in ordinary fluid mechanics.

(2) Equation of conservation of momentum, which is altered by the forces enumerated above. In particular, the ponderomotive force per unit volume is given by $\mathbf{J} \times \mathbf{B}$ where \mathbf{J} is the vector current density and \mathbf{B} the magnetic flux vector, both measured in the laboratory.

(3) Equation of energy conservation; the same as in ordinary fluid mechanics with the addition of the Joulean dissipation $\mathbf{E}' \cdot \mathbf{J}'$. The primes indicate that the electric field and current density are measured in a frame of reference moving with the fluid. In the nonrelativistic case and for zero space charge, we have $\mathbf{E}' = \mathbf{E} + \mathbf{q} \times \mathbf{B}$ and $\mathbf{J}' = \mathbf{J}$. The barycentric stream velocity is indicated by \mathbf{q} .

(4) Equation describing the thermodynamic state.

(5) Conservation of electric charge.

(6) Ampère's law.

(7) Faraday's law.

(8) Statement that the magnetic poles exist in pairs only.

(9) Ohm's phenomenological law. Equations (1) to (3) are the conservation equations. Equations (5) to (8) are Maxwell's equations. For a large number of problems, the phenomenological coefficients of electrical conductivity and the like are assumed to be scalar quantities. This implies that the collision frequencies among the particles are much higher than the cyclotron frequency associated with the tendency a charged particle has to rotate around a magnetic line under the influence of the Lorentz force. This means that the transfer of electric charge, mass, momentum, and energy is not realized in a preferential direction.

Physically, the magneto-fluid-mechanic system of equations is coupled in the following sense: A velocity field \mathbf{q} cutting magnetic lines of flux \mathbf{B} gives rise to an induced current whose magnitude is given by $\mathbf{J} = \sigma (\mathbf{q} \times \mathbf{B})$. At the same time the fluid feels an induced body force equal to $\mathbf{J} \times \mathbf{B}$. On the other hand, it is apparent that the electric currents induced by the motion create, according to Ampère's law, a magnetic flux which distorts the original applied field. The basic mechanism of this distortion is the one created by the irreversibility introduced by the finite electrical conductivity, the same way that the distortion of the inviscid streamlines in ordinary fluid mechanics takes place by the action of viscosity.

Nondimensional Parameters and Some Important Theorems. In order to study the nature of the solutions as they emerge from different problems, we shall form a number of nondimensional parameters that can be extracted from the different equations. The order of magnitude of the inertia force per unit volume is given by $\rho V^2/L$ where ρ is the mass density, V the velocity, and L a characteristic length; the order of magnitude of the ponderomotive force $\mathbf{J} \times \mathbf{B}$, after using Ohm's law, is equal to $\sigma B^2 V$. Also, the order of magnitude of the viscous force is: $\mu V/L^2$. The ratio of the typical inertia force over the viscous force is called the Reynolds number (Re) and, from the above, is found to be: $Re = \rho V L / \mu$. The ratio of the ponderomotive force over the inertia force is given by $\zeta = \sigma B^2 L / \rho V$. The ratio of the ponderomotive force over the viscous force is equal to $(Re)\zeta$ and is defined in the literature as the square of the "Hartmann number," denoted by M . We have $M = B L \sqrt{\sigma / \nu \mu}$. The distortion of the magnetic field due to the hydrodynamic field can be studied best with the help of the following two equations:

$$\frac{d\Omega}{dt} = (\Omega \cdot \nabla) \mathbf{q} + \frac{\mu}{\rho} \nabla^2 \Omega$$

$$\frac{d\mathbf{H}}{dt} = (\mathbf{H} \cdot \nabla) \mathbf{q} + \frac{1}{\sigma \mu_c} \nabla^2 \mathbf{H}$$

In the above μ_c is the magnetic permeability and \mathbf{H} the magnetic field intensity. The first equation describes the diffusion of vorticity Ω , whereas the second can be obtained by a combination of Ampère's and Ohm's laws after elimination of the electric field by using Faraday's law. In the ordinary fluid mechanic case, the streamlines obtained

after solving the inviscid problem are distorted in regions of high vorticity through the mechanism of viscosity (last term in first equation): Similarly the magnetic field calculated in the case of ideal, nondissipative flow with $\sigma = \infty$ is distorted by the finite electrical conductivity (last term in second equation). The nondimensional number describing the influence of viscosity is the Reynolds number, and in perfect analogy as indicated by the above two equations, the magnetic field distortion is described by the number, $(Re)_m = VL/(\mu_e \sigma)^{-1}$ and is called the magnetic Reynolds number. When $(Re)_m$ is zero, the magnetic lines remain undisturbed, whereas in the limit $(Re)_m \rightarrow \infty$, the magnetic lines are frozen into the fluid in exactly the same way that vorticity is frozen according to Helmholtz's theorem. Mathematical similarities apart, the freezing of the magnetic lines with the motion, is evident in the case of $\sigma \rightarrow \infty$ from the following physical considerations: An observer moving with the barycentric velocity in a medium of infinite electrical conductivity can measure only a zero electric field and hence he could not cut magnetic lines, which means that the magnetic lines must move along with his speed. From this argument it also follows that the total change in the magnetic flux through a given surface moving with the stream must be zero for an infinitely conducting medium. Finally, the remark should be made that except for stellar and interspace applications where the velocities and (especially) characteristic lengths are high, $(Re)_m$ is a small number. The assumption $(Re)_m \rightarrow 0$ is a rather drastic one since it permits the uncoupling of Maxwell's equations from the conservation equations.

For the calculation of the ponderomotive force we can use Ampère's law ($\nabla \times \mathbf{H} = \mathbf{J}$) to find that $\mathbf{J} \times \mathbf{B} = (\nabla \times \mathbf{H}) \times \mathbf{B}$. Through regular vector operations, we can prove that $(\nabla \times \mathbf{H}) \times \mathbf{B} = \text{grad} (B^2/2\mu_e) + \text{div} (\mathbf{B}\mathbf{B}/\mu_e)$. One can identify the last term as one representing a tension equal to $B^2/2\mu_e$ acting along the lines of force, whereas the first one corresponds to an equivalent hydrostatic pressure equal to $B^2/2\mu_e$. This term is frequently called "magnetic pressure" and in different problems is found to behave precisely as the static pressure does.

Consider now the propagation of small disturbances in the form of acoustic waves for which the speed of sound for an ideal gas is proportional to $\sqrt{p/\rho}$. Now one can show through a linearization of the equations of conservation, assuming the presence of the magnetic pressure alone, that a small disturbance (for a gas of infinite electrical conductivity) will be propagated, in perfect analogy, with a speed equal to $\sqrt{B^2/\rho\mu_e}$. This is the so-called Alfvén speed, and these waves are called magneto-fluid mechanic waves. Of interest also are combinations of several mechanisms of propagation which might include sound and gravitational waves. Furthermore, one can show that if the magnetic lines are lengthened, the magnetic field intensity can be increased. Because of this property of the magnetic lines, along with the additional ones of distortion and propagation of

disturbances, the properties of the magnetic field are presented in loose terms as resembling very much those of rubber bands.

Applications. There are both astrophysical and terrestrial applications of magneto-fluid-mechanics. One of the earliest ones was perhaps suggested by Faraday, who thought to harness the river Thames with electrodes on its banks that would collect the induced electric current resulting from the flow of the river as it cuts the earth's magnetic field perpendicularly. Because of the small electrical conductivity of water, the small magnetic field of the earth and the small velocities, the interaction is too weak to be useful. However, with a mutually perpendicular magnetic field, flow, and induced current density fields, a large interaction is possible in the laboratory with hot ionized gases and strong magnetic fields. This area of research is called magneto-hydrodynamic power generation, and its popularity emerges from the fact that mechanical energy can be converted to electrical without thermally stressed rotating parts. As a consequence, higher temperatures can be imparted to the working medium with better thermal efficiencies. This scheme, under development now, seems to be limited by losses due to heat transferred from the hot gas to the outside, corrosion of the electrodes, and Hall current losses. (When the gyrofrequency of the ionized particles is high compared to their collisional frequency, the particles drift in a direction parallel to the flow, and as a result, the current in the direction perpendicular to the flow, to be collected by the electrodes, diminishes. The Hall effect can be turned to some advantage if it is designed to be substantial and if the current in the direction of flow is the one to be collected.)

One of the earliest astrophysical applications of magneto-fluid-mechanics was in the area of solar physics and in particular the sunspots. Sunspots were seen and studied with the help of a telescope by Galileo about 1610. Three hundred years later, Hale discovered, through the Zeeman effect, that the magnetic field in the sunspots is very high (of the order of several thousand gauss). It was, however, in the middle 1930's and in particular after the last world war that an explanation was sought in which the magnetic field was involved. At the writing of this article, there is no complete sunspot theory. However, the majority of workers in this area agree on the following rough picture. Because of mechanical equilibrium considerations, the pressure is the same at a given distance from the center of the sun in the sunspot proper or in the photosphere which is free of a magnetic field. This means that the magnetic pressure plus the static pressure in the sunspot region must balance the static pressure in the photosphere, a fact that implies that the static pressure in the sunspot is smaller. If we picture the sunspot magnetic lines to be radial, the pressure gradient in this direction is independent of the magnetic field and balances exactly the gravitational force per unit volume pg . Hence p is constant inside and outside the sunspot. Since the static pressure is proportional to density and

temperature, the above arguments compel us to accept a lower temperature inside the spot with a resulting darkening. The only question that rises is whether the order of magnitude of the magnetic pressure is enough for the effect to be significant. This seems to be so. If we assume a magnetic field of 1500 gauss (typical in a sunspot), the magnetic pressure is about 0.1 of an atmosphere which is the typical pressure in the photosphere.

An explanation for the bipolar nature of sunspots and the difference in the sign of their polarity has been offered. The differential rotation of the sun is invoked. The toroidal magnetic lines of the sun's field lying on its surface are twisted, since for very high electrical conductivity, they are frozen with the motion. As a result, the magnetic intensity is amplified and so is the magnetic pressure. Simple considerations based on the observed kinematics of the differential rotation establish the location in latitude with time where the intensities will be high enough to give rise to sunspot activity. The result compares favorably with observations. In fact, it can be shown that the sunspot activity migrates, time-wise, from the higher latitudes towards the equator as observations show. Because the twisted field is symmetric with respect to the equatorial plane, this model describes correctly the symmetry of the activity in the north and south hemispheres along with the fact that the polarity between two symmetric sunspot pairs is opposite in sign.

Efforts have been made to discover the mechanism for the generation and maintenance of cosmic magnetic fields, such as fields in stars, the earth, and galaxies. The most promising direction seems to lie in the so called "dynamo theories." Here, some general magnetic field is assumed (not necessarily strong), which upon interaction with the motion of a conducting medium (convective, or motion due to Coriolis forces), induces currents which reinforce the original magnetic field. As the magnetic field is reinforced, the ponderomotive force suppresses the motion until some kind of a steady state for both the motion and the magnetic field is reached.

Magneto-fluid-mechanics also studies problems related to magnetic confinement of plasmas and their stability to small disturbances. Consider for instance the so-called "pinch effect." Here, a strong current is passed through a cylindrical column made up of a plasma. The axial current filaments create an azimuthal magnetic field (the magnetic lines are then rings with the cylinder axis as the locus of their centers,) and as a result, a ponderomotive force is induced which compresses the plasma radially*. Through this confinement, it is hoped that temperatures of the order of 10^6 to 10^7 K will be created so that thermonuclear fusion can take place. Such configurations are normally subject to instabilities. Consider, for instance, the case in which a small "kink" is

formed in a cylindrical plasma column, such that the rings in the concave side are pressed together, whereas the rings in the convex side are separated. As a result, the magnetic flux (and hence the magnetic pressure) will be higher on the concave side resulting in a force tending to increase the concavity. We say that this configuration is unstable, since the force induced by the imposed disturbance acts in a destabilizing direction. Note that in this configuration, the center of curvature of the undistorted plasma boundary falls inside the plasma. One can now create another example in which the curvature of the confining undistorted boundary of the plasma is opposite (the center of curvature falls in the vacuum) and show that the configuration will be stable. We can then state that a sufficient condition for stability is met when the magnetic lines are everywhere convex towards the plasma. If the magnetic lines induced by the currents going through the plasma are in an unstable configuration, externally imposed magnetic fields can be used in order to "stiffen" the configuration.

The "aurora borealis" can be explained in terms of the interaction of the solar wind (due to the continuous expansion of the solar corona with a velocity of about 500 km/sec) with the geomagnetic field. The inertia associated with this "wind" will penetrate the magnetic lines of the earth, only up to the point where the induced magnetic pressure is smaller than these inertial forces. The earth's magnetic field falls off with the inverse third power from the center of the earth. Knowing the mass density and the velocity of the solar wind, we can locate the remotest magnetic line from the earth, that is strong enough to stop the penetration of the solar corpuscles. When this happens, these particles will glide along this magnetic line and eventually will come to the foot of this line at the surface of the earth. An elementary computation shows that the latitude of this line is the one where the "aurora borealis" is observed. (see AURORA AND AIRGLOW).

Convective motions can be effectively subdued by the presence of a magnetic field. Consider, for instance, the convection in a thin horizontal layer due to heating from below. Convective cells (Bénard Cells) will be formed when the buoyant force is enough to counterbalance the viscous force of the motion. At the same time, balance of energy dictates that the heat convected upwards be equal to the heat conducted from the hot source at the bottom. The ratio of these two energies is called the "Rayleigh number," and for a given geometry, it must be higher than a critical value for the Bénard cells to appear. However, when a magnetic field is present, the ponderomotive force inhibits the motion and at the same time changes the geometry of the cell. The extent of this inhibition is given by the Hartmann number (defined earlier) so that the critical Rayleigh number is higher for higher Hartmann numbers. Available laboratory experimental results reconfirm the findings of this theory. On a cosmic scale, it has been hypothesized that the roll-like granulation in the sunspot penumbra is

* Pinch-effect devices are also useful in metallurgy where molten metals can be confined away from solid boundaries in order to remain pure.

the result of the magneto-fluid-mechanic inhibition of the motion inside regular photospheric convective cells.

Magnetic fields are also known to inhibit the onset of turbulence. For instance, consider the flow of mercury in a channel. Experiments have shown that the flow can be laminar well above the critical Reynolds number of 2000 or so, if a coil is wrapped around the pipe thus creating an axial magnetic field. The small disturbances perpendicular to the direction of the main stream will be damped out through the action of the induced retarding ponderomotive force.

Many other cosmic scale phenomena seem to be explainable through magneto-fluid-mechanics. To list but a few, there are the solar flares and filaments, the spiral structure of some galaxies, the heating of the solar corona, explosion of magnetic stars and many others. Although order-of-magnitude analyses have been suggested to explain some of these phenomena, there are no complete self-consistent theories. Such theories seem to demand a simultaneous satisfaction of all the conservation and electromagnetic equations -- a formidable, if ever possible, task. On the terrestrial scale, many applications have been undertaken, and some of them are dependent upon technological development rather than fundamental physical understanding. To give a few more examples, in addition to those already mentioned, we list magneto-fluid-mechanic liquid metal pumps, and flow meters, propulsion devices based on the acceleration of a neutral plasma through which a current and a normal magnetic field from the outside are supplied (an area called "plasma propulsion"), or a device in which positive ions (such as the ones easily produced by alkali metals) are accelerated with an electric field (ionic propulsion). Other examples are devices to reduce the heat transfer in reentry objects by using the decelerating action of a magnetic field carried by the vehicle or to use the ponderomotive force as a control force when needed for the navigation of space crafts.

MAGNETOMETRY

The term "magnetometry" designates the scientific approaches for measuring the magnetization of materials and static magnetic fields. Magnetometers are scientific instruments used for the following purposes: (1) to measure the magnetic moment of the specimen and to determine the magnetization of materials; (2) to calibrate electromagnets and permanent magnets used in the production of magnetic fields in the laboratory, and (3) to measure the strength of magnetic fields and their components on or near the surface of the earth, as well as in space.

Four distinct principles are basic to the design of magnetometers: magnetostatic action, electromagnetic induction, deflection of carriers in semiconductors, and precession of nuclear and electronic spins. This article selects the basic features of some representative instruments from among the many available types.

The Classical Astatic Magnetometer. This is used to determine the magnetic moment of rod-shaped samples. The specimen can be exposed to the controllable homogeneous magnetic field produced in the center region of a solenoid which is appreciably longer than the specimen. Its magnetic moment is characterized by strength and direction of the field at a known distance from the sample. Two equivalent, permanent magnet needles horizontally placed and rigidly linked by a nonmagnetic rod in a vertical position comprise the measuring system. Arranged in antiparallel alignment, the needles have a wide distance between them, as compared to length. This astatic system, unaffected by the earth field, is suspended on a calibrated torsion wire. The axis of the test specimen is placed perpendicular to the axis of the lower needle and in its plane of rotation. It is possible to cancel the field of the magnetizing solenoid at the location of the sensing needle by means of a magnetically opposing solenoid located in the same plane. The magnetic moment of the specimen can be derived from the angular deviation of the needle occurring from the action of the static field. However, in order to determine the magnetization in this manner, there must be provision for homogeneous magnetic field throughout the sample volume. Therefore, the sample should be machined into a rotation ellipsoid with its long axis pointing in the direction of the needle. Calibration is by means of the well-defined moment of a coil.

With a modified astatic magnetometer, the magnetic properties of extremely small specimens in the form of fine wires or films have been measured. The specimen is arranged parallel to the axis of the astatic system and a short distance from the closely spaced short needles, in order that each needle will sense the pole of the neighboring sample. Under this method, films as thin as 10^{-5} cm, weighing less than 1 mg, have been investigated.

Concurrently, with the evolution of microwave techniques in the last two decades new magnetic materials suitable for these high frequencies have been discovered. Single crystals of ferrite, garnet,

and related substances have become significant, both technically and scientifically. As a result, new types of magnetometers have been invented to determine the magnetization of extremely small samples. The new instruments are based on the relative periodic displacement of the dipole field of the specimen against pickup coils and subsequent amplification of the small induced ac voltages.

The Vibrating Sample Magnetometer. This makes use of a mechanical oscillator that can be either a loudspeaker or a motor. The sample, attached to the lower end of a nonmagnetic shaft, moves up and down, between and parallel to the pole faces of an electromagnet. Amplitude of the oscillation is approximately 2 mm, the frequency approximately 80 cps with loudspeaker drive. The sample stays within the homogeneous region of the magnetizing field. Two series opposing signal coils with approximately 20,000 turns each are located on each side of the sample, with axes parallel to its motion and perpendicular to the exciting field.

For small samples, only dipolar field lines are linked with the signal coils. The magnetic moment can be derived directly by comparison with the voltage excited by a standard sample of known magnetization (nickel). The vibrating sample magnetometer can be operated over a wide range of temperature with a maximum sensitivity (defined as the sample magnetic size needed for a 1 to 1 signal-to-noise ratio) of 10^{-6} to 10^{-3} emu.

The Vibrating Coil Magnetometer. In this instrument, the sample is kept in a fixed position in the homogeneous region of the magnetic field between the pole faces. The signal coil oscillates at approximately 40 cps, its axis and velocity vector being collinear with the dipole axis of the specimen. The distance between coil and sample is large enough to allow for installation of temperature- and pressure-generating apparatus to include the sample. Special precautions have to be taken to eliminate the signal produced by the curvature of the magnetizing field. The measurement, which can be recorded, is continuous. The sensitivity as reported is about 10^{-2} emu.

The Pendulum Magnetometer. This is a rather simple apparatus which utilizes the ponderomotive force which a sample experiences in an inhomogeneous magnetic field. The device is based on the perception that this force is (for small deviations from the position of maximum field strength) proportional to the displacement perpendicular to the field lines between the hemispherical pole pieces of an electromagnet. This condition causes a simple harmonic motion. The specimen is fastened to a light bar whose movement is constrained only in the direction of its length and without rotation by a quinquefilar suspension. The magnetization is determined from measurements of the periods of oscillation with and without magnetic field.

The Vibrating Reed Magnetometer. This has been developed as a result of the above-described principle for obtaining a harmonic oscillation between appropriately shaped pole faces. The

pendulum is replaced by a metallic reed of nonmagnetic material, and the sample is attached to one end. The vibration of this spring is excited by a piezoelectric transducer driven from an oscillator; the resonance frequency of the reed is observed with and without field. The magnetization can be calculated by comparison with a reference sample. Accuracies of about 1 per cent can be obtained on specimens with magnetic moments of 50 emu. The vibrating reed magnetometer can also be used for measurements at elevated temperatures.

The term "magnetometer" was first applied to instruments that measured static magnetic fields. The magnetometric principle was originally developed for the study of the earth's magnetic field and its peculiarities. There is a basic identity in present-day methods used for measuring fields produced in the laboratory and the field pattern on and above the surface of the earth. Specific design of instruments and their accessories are tailored to meet particular requirements; the magnitudes of the fields to be analyzed range from approximately 10^{-5} to 10^{-6} oersted.

The "Gaussmeter" or "Fluxmeter." This is a laboratory instrument widely used for the calibration of electromagnets. It comprises a small dc generator. A small generator coil is wound on a nonmagnetic core, placed at the end of a 3 to 4 foot long axis, and driven by an ac motor with constant speed of revolution. The induced sinusoidal voltage is rectified by a commutator and read on a voltmeter calibrated in magnetic field units. The device is inherently linear; a commercial version allows full-scale readings from 2.5 to 120,000 gauss with different coils (\pm per cent accuracy). The instrument also yields an approximate determination of the direction of the field vector.

The Earth Inductor. This geomagnetic survey instrument is used for measurement of the inclination (or magnetic dip) of the earth field. A coil, connected through commutator and brushes to a sensitive galvanometer, is rotated about its diameter by a hand-powered flexible shaft. When the rotation axis of the coil is brought in line with the earth field, the galvanometer will read zero; the inclination of the axis against the horizontal plane can be read with an accuracy of approximately 0.1°.

The Classical Magnetometer of Gauss. This instrument determines the horizontal field intensity of the earth field in stationary observatories. Two measurements are required: (1) the measurement of the period of a permanent magnet, which is vertically suspended on a torsion fiber, when it oscillates in the horizontal plane about the magnetic meridian; (2) the measurement of the deflection angle, which a magnetic needle experiences attached to the same suspension, when the permanent magnet acts at a preset distance in a preferred position together with the earth field upon the needle. This method is an absolute one.

The Sine Galvanometer. This is an absolute instrument for the determination of horizontal intensity. With it, the suspended detector magnet is acted upon by a field produced by a calibrated

coil and the horizontal field component. Accurate measurements of the coil current and deflection angle of the needle are required.

The Flux-gate Magnetometer. This magnetometer, which lends itself to aircraft application, has been used successfully for detecting magnetic anomalies and for exploring the earth's surface in search of mineral deposits. It has also been used for submarine detection. The operation of this instrument is based on the change of permeability of a highly sensitive material in weak fields. A device known as the flux gate exploits this effect. It contains two permalloy cores in parallel position. A coil is wound on each of the cores; the two windings are opposed in their polarities and connected in an impedance bridge circuit in such a manner that an ac voltage supplying the bridge will not produce a diagonal voltage. The bridge is balanced in the absence of an external field. If a component of the earth's field parallels the axis of the core, the bridge becomes unbalanced due to the opposing magnetic biases. The voltage produced then acts upon servomechanisms. Measurement of the field is as follows: Three mutually perpendicular flux gates are mounted on a platform that can be rotated by servomotors in two perpendicular planes. Activated by the diagonal voltage from one flux gate, each servomotor rotates its twin core, decreasing the unbalance and holding the cores in zero position. The combined action of two gates then brings the cores of the third gate into the direction of the field. An additional field winding encloses both cores of the third gate; a servomechanism controlled by the diagonal voltage of this gate provides a current through the field winding, in order to annul the earth's field. The magnitude of this current determines the strength of the earth's field. The flux gate magnetometer is sensitive to variations of about 1 gamma ($\sim 10^{-5}$ oersted).

Hall-effect Device. In recent years, investigations on semiconductivity led to the Hall-effect device for measurement of magnetic fields. Hall voltage occurs in a current-carrying sample of semiconducting material perpendicular to the current and perpendicular to an applied static magnetic field. The magnitude of the voltage is proportional to the field. Low noise level is inherent in this device; dimensions of the sensing element can be kept rather small. The Hall voltage amounts to approximately 100 mV at 10 000 gauss, with 100 mA current. The operating temperature range is between -40 and $+85$ C for a commercial device. The use of the Hall-effect device is mainly restricted to the laboratory.

The Nuclear Precession Magnetometer. This device uses the phenomenon of nuclear magnetic resonance. This method covers a wide field range with high accuracy in determining field strengths. Nuclear probes are extensively used for determination of fields and field gradients of laboratory magnets. The technique lends itself to telemetering the information; it is capable of operating at small fields. Therefore, the proton-precession magnetometer is employed in space probes and satellites.

The nuclear resonance method is characterized

by an outstanding feature: the sharp line width for absorption of rf power by the appropriate types of nuclei when exposed to a magnetic field. The resonance frequency for H^1 is 4257.8 cps/gauss and 1654.6 cps/gauss for Li^7 . The probes used for calibrating magnets are a few millimeters in size. The resonance frequency can be determined precisely by counting procedure.

For geomagnetic measurements, a larger probe (water) is required to obtain a sufficiently strong response at small fields. First, the probe is exposed for a few minutes to a strong field (100 gauss) perpendicular to the earth's field, in order to obtain sufficient polarization. On sudden removal of this field, the spinning protons precess about the earth's field, inducing a voltage in a coil suitably placed. The signal duration is approximately one second, at which time it relaxes toward zero. Nevertheless, accurate frequency measurements can be made within this time. This total-intensity nuclear magnetometer has been improved for the determination of vector field measurement.

MAGNETOSTRICTION

When a polycrystalline nickel sample is placed in a magnetic field, it contracts along the field direction by about 30 parts per million and elongates in the transverse direction by about half that amount. There is also a small volume change. Such changes in dimension of magnetic materials with variation of magnetic field strength or direction, are termed *magnetostriction*. They are measured by strain gages, optical dilatometers, capacitance variation, and x-ray analysis.

Below the Curie temperature, magnetostriction in weak fields is determined by domain rotation, becoming appreciable at fields near the knee of the *B-H* curve.

In saturating fields there is still a small linear dependence of magnetostriction on magnetic field strength, and above the magnetic ordering temperature magnetostriction is, except in rare instances, quadratic in magnetic field strength.

Field strength dependent distortions in the saturated and paramagnetic regions, designated *forced magnetostriction*, are due to the paraprocess, the induction of a moment by the field.

The saturation magnetostriction of single crystals depends upon the direction of the (sublattice) magnetization, α , and the direction of measurement, β , with respect to the crystal axes. In a cubic crystal (with collinear sublattices), to lowest order,

$$\delta l = \lambda_0 + \frac{1}{2}\lambda_{100}[\alpha_1^2\beta_1^2 + \alpha_2^2\beta_2^2 + \alpha_3^2\beta_3^2] + 3\lambda_{111}[\alpha_1\alpha_2\beta_1\beta_2 + \alpha_2\alpha_3\beta_2\beta_3 + \alpha_3\alpha_1\beta_3\beta_1] \quad (1)$$

Birss¹ gives higher order expressions for cubic and hexagonal symmetry and references for other symmetries. The distortion of an unmagnetized polycrystalline material placed in a saturating magnetic field can be calculated by averaging over directions in Eq. (1). For cubic polycrystals the change in length parallel to the field accompanying magnetization is given by

$$\bar{\lambda}_H = \frac{2\lambda_{100} + 3\lambda_{111}}{5} \quad (2)$$

Birss¹ emphasizes the unreliability of the assumption of initially random domain distribution implicit in Eq. (2).

Magnetostriction coefficients vary greatly, depending upon the material, temperature, and magnetization state. For pure iron at room temperature, the saturation magnetostriction constants are $\lambda_{100} \sim 20 \cdot 10^{-6}$; $\lambda_{111} \sim 20 \cdot 10^{-6}$, while for alloys near 80Ni-20Fe (weight per cent) these constants are almost zero. The cobalt ion causes a large magnetostriction; for cobalt ferrite $\lambda_{100} \sim -500 \cdot 10^{-6}$ while for nickel ferrite $\lambda_{100} \sim -30 \cdot 10^{-6}$. The largest known magnetostriction is that of dysprosium metal.² As a magnetic field is rotated in the basal plane of this hexagonal crystal, there is a basal plane distortion of almost one per cent, at liquid nitrogen temperatures and below.

The source of magnetostriction is the dependence of magnetic energy on strain. Because the elastic energy is quadratic in strain while the magnetoelastic energy is linear in strain, the minimum free energy occurs at nonzero strain. For example, in a cubic crystal the equilibrium shear strain ϵ_{xy} is given by

$$\epsilon_{xy} = \frac{B_2(T, H)}{c_{44}} \alpha_x \alpha_y \quad (3)$$

Here c_{44} is the elastic constant, the α 's are magnetization direction cosines, and $B_2(T, H)$ is a magnetoelastic coefficient representing the variation of magnetic energy (magnetic anisotropy, dipolar, anisotropic exchange) with strain.

Quantum mechanical calculations of the magnetoelastic coefficients are in a somewhat more satisfactory state in the case of nonconductors than for metals. Extensive calculations by

Tsuya of the B coefficients of the spinels are reviewed by Kanamori.³

The temperature dependence (and "forced" field dependence) of the magnetostriction coefficients is due to statistical averaging as the individual spins fluctuate around the average magnetization direction α . For some materials this temperature dependence can be expressed entirely in terms of a known function of the (sublattice) magnetization. For ferrimagnets⁴

$$\lambda_i(T, H) = \sum_n \lambda_i^n(0) f_i(m_n(T, H)) \quad (4)$$

That is, the magnetostriction coefficient $\lambda_i(T, H)$ is the sum over sublattices of temperature independent sublattice magnetostriction coefficients ($\lambda_i^n(0) - B_2^n(0)/c_{11}$) times a function f_i of the sublattice magnetization $M_n(T, H)/M_n(0)$. At sufficiently low temperatures this function reduces to

$$f(m_n(T, H)) = \left[\frac{M_n(T, H)}{M_n(0)} \right]^3; T \ll T_c \quad (5)$$

for both λ_{100} and λ_{111} .

Bozorth,⁵ Carr,⁶ and Kneller⁷ give references on magnetostriction and discuss measurement techniques.

MANY-BODY PROBLEM

Scope and Definition. A large part of the experimental data of physics is concerned with natural objects which may be looked upon as being made up from smaller bodies. For example, we may think of the solar system as an object composed of the planets and the sun; ordinary matter, in solid, liquid or gaseous form, as composed of molecules and atoms; atoms and molecules themselves as made up from nuclei and electrons; and finally, the nuclei as composed from neutrons and protons. We shall call the composite object the system, and its constituents, the particles; and note that it seems most reasonable to suppose that the properties of the system can be explained on the basis of the law of interaction between the particles and the laws of dynamics.

The latter may be classical or quantum mechanical according to the demands of the situation. At each level of refinement we refrain from asking about the internal structure of the particles. This is to achieve a natural simplicity of description; but still, at each such level, we have a rich variety of natural phenomena to explain.

The many-body theory is not concerned with any fundamental or complete explanation of nature. Its chief aim is to formulate schemes according to which calculations of certain physical quantities can be performed theoretically and the results can be compared with experimental measurements. It is inherent in its methods that the number of particles is considered as being large, and no attempt is made to find all the details of motions of the particles—a characteristic which distinguishes it from the so-called one-, two- or three-body problems.

Since the early 1950's there has been a great deal of activity in the theory of quantum mechanical many-body systems such as nuclei, solids and fluids. As a result, the term many-body problem has come to mean, almost exclusively, the theory of such systems at or near the absolute zero of temperature. The latter qualification serves to distinguish the many-body problem as such from the closely related field of STATISTICAL MECHANICS. These modern developments are based on the observation that when the number of particles is so large that it may be considered effectively infinite, then the system becomes very similar to that of interacting fields—except for the nature of interactions considered and the general formal methods of quantum field theory and quantum electrodynamics may be used with advantage.

There is only one general theorem in many-body theory; it is known as Poincaré's theorem. Roughly speaking, it states that any given initial state of a finite many-body system will be repeated provided one waits long enough. The quantum mechanical form of this theorem states that all observables in a finite system are almost periodic functions of time. This theorem has not had much practical use but has played an important role in discussions concerning the foundations of statistical mechanics.

The so-called many-body theory is mainly a collection of special approximate methods developed for particular problems. The chief common features of some of the methods, especially the ones connected with modern developments, will now be described.

Reduction to an Equivalent System of Non-interacting Particles. The very fact that we can recognize the constituent particles leads us to believe that in the lowest approximation we may neglect their interactions. This approximation is already quite successful in derivation of perfect gas laws and electron theory of metals. A slightly different form of this assumption occurs in the case of atoms, which are treated as systems of non-interacting electrons moving in the field of force of the nucleus. For planetary systems a similar approximation is used.

The normal mode analysis of a lattice provides an example where a transformation of coordinates is used to achieve such a reduction. Instead of considering the coordinates of individual particles which interact with each other through harmonic forces, one considers certain linear combinations of displacements, the modes. In terms of the new variables there are no interactions and the solution is immediately obtained. This is an example of a *transformation* which introduces a *collective* description of the system.

Another type of situation occurs in nuclear theory, where it is found that a shell-model of the nucleus, built in analogy with the atomic shell-model, is very successful. The non-interacting particles of this model are called neutrons and protons, but interaction between them which must be used in this model is vastly different from that observed in two-body scattering experiments. As a first approximation one can completely ignore the mutual interaction and assume that the particles move in a common one-body potential. This circumstance suggests that what are called neutrons and protons in this model are not the same as the free ones but are only some *quasi-particles* which are appropriate to the model and happen to have many properties in common with actual particles. An analogous situation occurs in some solids where the electrons are observed, by means of cyclotron resonance experiments, to possess an effective mass different from the mass of free electrons.

Effective Field Method. This is one of the methods of taking into account the mutual interactions of the particles. One starts with a given motion of particles, e.g., from an approximation of the type described in the last paragraph, and calculates the field of force experienced by one of the particles under the influence of all the others. As a further refinement the field may be made *self-consistent*, that being the situation when the motion produced under the influence of the field is the same as that which generated it. But for the approximations made in the course of calculation, such as omission of the effects of correlations among the particles, a fully self-consistent theory would be a complete theory.

Examples are: Hartree-Fock theory, Fermi-Thomas approximations, Brueckner theory of nuclei, Wigner-Seitz cell model in solid state theory, and several others.

Collective Motion Theory. In some phenomena, such as propagation of sound and plasma oscillations, it is clear that many particles are performing coordinated movements. To study such cases, one introduces some collective variables in addition to the usual ones, and the Hamiltonian is re-expressed in terms of these mixed variables. *Subsidiary conditions* have to be imposed upon this extended system of variables to preserve the original number of degrees of freedom. The collective variables should be such that there is no appreciable interaction between these and other degrees of freedom. When quantum mechanics is applicable, the collective motions are also excited in quanta which for all practical purposes may be

treated as new (quasi) particles. The stability of collective motions is then expressed in terms of the lifetimes of quasiparticles. Solid-state physics is particularly rich in exhibiting collective motions. Quasiparticles associated with some of them are: the phonons (sound, lattice vibration); the polarons (electron and its polarization field in dielectric); and the excitons (electron-hole excitations in insulators). Collective motions in nuclei can also be interpreted in a similar manner. Superconductivity and superfluidity are also examples of collective motion. The quasiparticles responsible for superconductivity are electron pairs with equal and opposite momenta.

Use of Techniques of Field Theory. With these techniques it is possible to obtain formal expressions which represent the effect of interparticle interactions to any order in perturbation theory. By carrying out rearrangements and partial summations of terms in perturbation series it is possible to see that, as far as the motion inside the system is concerned, the relationship between the coordinates and momenta and the potential and kinetic energies is changed in such a way that it has to be described in terms of an effective mass and an effective interaction, which differ from the original quantities in a known way. In certain cases these effects can be calculated and are finite.

Brueckner's theory of nuclear matter is an example of this type. The effective mass is found to depend on the momentum of the particle inside the system, and the effective interaction, the so-called t - or K -matrix, is given by an integral equation involving the original interaction. A self-consistent calculation of the properties of the system (nuclei or atoms) can be based on this understanding.

Similar techniques can be used for studying collective motions. An example is the treatment of electron gas by Gell-Mann and Brueckner.

Perhaps the greatest advance has been made in the theory of superconductivity, where variational and canonical transformation methods have been used.

A combination of all these methods is needed to study the difficult problem of relationship between various excitations, i.e., the interaction between various quasiparticles of a many-body system. One of the most useful tools in these calculations is the representation of matrix elements by means of diagrams, first introduced by Feynman. Many of these methods were first developed in connection with the theory of interacting fields and they are usually employed in many-body problems for the limiting case of an infinite number of particles, but these restrictions are not essential; in fact, they are quite general methods of treating arbitrary quantum mechanical systems.

MASER

The term "maser," coined by Townes and co-workers who pioneered this field, stands for *m*(icrowave) *a*(mplification by) *s*(timulated) *e*(mission of) *r*(adiation). "Microwave" has proved restrictive; stimulated emission amplifiers have operated in the UHF (~ 300 mc/sec), and at infrared, visible, and ultraviolet frequencies (see LASER). The principal advantage of the maser amplifier is its small intrinsic internal noise: the equivalent *noise input temperature* is but a few degrees Kelvin. The theoretical minimum noise input temperature is hf/k , where h is Planck's constant, k is Boltzmann's constant, and f is the signal frequency. This is 0.48 K at $f = 10$ Gc/sec (gigacycles per second) or 10×10^9 cps. Maser oscillators can generate exceedingly monochromatic radiation, (e.g., the ammonia maser has a short-term frequency stability of ~ 5 parts in 10^{12}), and may prove to be the only practicable sources of coherent sub-millimeter wavelength radiation.

Stimulated Emission of Radiation. Because its energy is quantized, a molecule (here a generic term) can exchange energy with the electromagnetic radiation field only in discrete amounts (quanta). The emission or absorption of a quantum (photon) is associated with a transition between molecular energy states. For two states, $|m\rangle$, $|n\rangle$ of energies W_m , W_n , ($W_m > W_n$), the frequency f_{mn} of the radiation accompanying the (permitted) transition between them satisfies the Bohr condition

$$hf_{mn} = W_m - W_n \quad (1)$$

A molecule in state $|n\rangle$, exposed to radiation of frequency f_{mn} and energy density u , has a probability per unit time $u \times B_{nm}$ (B_{nm} is a constant) of absorbing a photon hf_{mn} and reaching state $|m\rangle$. There is also a probability $u \times B_{mn}$ that a molecule in the upper state $|m\rangle$ will *emit*

a photon hf_{mn} and return to the lower state $|n\rangle$. The upper state molecule is *stimulated* to emit radiation of frequency f_{mn} by the radiation field at this frequency. Stimulated emission, like absorption, is a process which is *phase coherent* with the incident radiation. Thermodynamical arguments by Einstein (1917) showed that

$$B_{nm} = B_{mn} \quad (2)$$

A molecule in the upper energy state $|m\rangle$ may also revert to the lower state $|n\rangle$ by *spontaneously* emitting radiation of frequency f_{mn} . This spontaneous emission is a random process, which is phase incoherent with any incident radiation and is therefore a source of noise in a maser.

The spontaneous emission probability A_{mn} is given by

$$A_{mn} = B_{mn} \cdot hf_{mn} \cdot \rho_f \quad (3)$$

where ρ_f is the number of wave modes per unit volume per unit frequency range open to radiation of frequency f_{mn} . Table I shows values of ρ_f under various conditions; c is the velocity of light, v_g is the group velocity of radiation.

TABLE I

Environment	ρ_f
Enclosure large compared with the wavelength c/f_{mn}	$8\pi f_{mn}^2/c^3$
Single mode resonant cavity, volume V , width of half-power response Δf	$2/(\Delta f \cdot \pi V)$
Waveguide, cross section A	$1/Av_g$

In the microwave region (say, 1 to 100 Gc/sec), $A_{mn} \ll B_{mn}$; spontaneous emission is therefore negligible except as a source of noise. However, maser spontaneous emission noise is usually exceeded by noise arising from losses in ancillary microwave circuit elements.

Molecular transitions are excited by either the electric or magnetic component of the radiation field, depending upon whether the change in molecular energy is primarily electric or magnetic in character. Each radiative transition has associated with it an effective oscillating electric or magnetic moment, usually dipolar. The probability B_{mn} given above depends directly on this dipole moment and inversely on the frequency spread (line width) δ of the transition.

Conditions for Amplification. Suppose radiation of frequency f_{mn} is incident on an assembly of molecules with an allowed transition at this frequency [Eq. (1)]. Let the number of molecules in the upper state $|m\rangle$ be N_m , and in the lower state $|n\rangle$ be N_n . If the incident radiation energy density is u , the power absorbed by the molecules will be

$$P_A = N_n u B_{mn} h f_{mn} \quad (4)$$

and the power emitted will be (see equation 2)

$$P_E = N_m u B_{mn} h f_{mn} \quad (5)$$

Since at microwave frequencies spontaneous emission is negligible, the condition for amplification is

$$P_E > P_A; \text{ i.e., } N_m > N_n \quad (6)$$

There must be an excess of molecules in the *upper* energy state of the transition associated with the signal frequency.

For thermal equilibrium at temperature T , Boltzmann statistics give

$$(N_m/N_n) = \exp(- (W_m - W_n)/kT) \\ \exp(-hf_{mn}/kT) \approx 1 - (hf_{mn}/kT) \quad (7)$$

at microwave frequencies, where $hf \ll kT$. Clearly a molecular system in thermal equilibrium is thus always absorptive. Equation (7) allows the definition of an "effective temperature" T_m for an emissive system; Eq. (6) and (7) show that T_m will be a "negative" temperature, and that $|T_m| \rightarrow 0$ for $(N_m/N_n) \rightarrow \infty$. Obtaining an emissive condition, obtaining a "negative temperature," and obtaining "population inversion" are thus synonymous. The excitation of a molecular assembly to an emissive condition is perhaps the crux of the maser problem. The schemes used depend on the conditions and on the molecular system. Discontinuous methods (pulse inversion, adiabatic fast passage) can be used, but the account here is confined to the principles of continuous methods. In a gas, actual separation of the upper-state molecules may be possible. For example, the upper-state molecules for the 23.87-Gc/sec ammonia maser transition tend to increase their energy in a static electric field, while the lower-state molecules tend to decrease their energy (Quadratic Stark effect). In an inhomogeneous electric field, the wanted upper-state molecules will therefore drift to the low-field regions. An electrode system (with geometrical axial symmetry) which gives a low-field region along the symmetry axis will therefore confine the upper-state molecules in a beam along this axis while rejecting the lower-state ones.

Most masers operate on the multilevel excitation scheme, requiring an input of energy ("pumping") at some frequency other than the transition frequency; forms of energy other than electromagnetic may also be used. The principles of the scheme will be illustrated by reference to a molecule having 3 levels with energies $W_1 < W_2 < W_3$, such that all transitions between levels are allowed. (The transitions other than the signal transition need not radiate electromagnetically). In thermal equilibrium the number densities $(n_i)_e$ of the particles in the different states (*i*) will satisfy

$$(n_1)_e > (n_2)_e > (n_3)_e$$

The frequencies f_{32}, f_{21}, f_{31} are defined from

$$f_{mn} = (W_m - W_n)/h$$

Suppose now by some means, that the transition $1 \rightarrow 3$ is *saturated*, i.e., $n_1 \approx n_3$. (This might be achieved by a sufficiently strong electromagnetic field at frequency f_{31} —known as the "pump")

frequency). Under these conditions, it may happen either that $n_2 > n_1$, or that $n_3 > n_2$. In the first case, amplification will be possible at f_{21} ; in the second case, at f_{32} , provided that the appropriate transition is electromagnetically radiative.

There are many variants on the simple scheme just described. The frequency f_{31} may lie in the optical region (OPTICAL PUMPING); the excitation may be by collision processes in a gas discharge; or more than three levels may be involved, and pump frequencies lower than the signal frequency can sometimes be used.

Maser Materials. Maser action has been achieved in gases (e.g., ammonia, formaldehyde, hydrogen, rubidium vapor) and liquids (e.g., protons in water) but the most important maser materials are the solid-state ones, since these have a high concentration of active centers in a small space. Present emphasis is on the use of certain paramagnetic ions diluted in a host crystal lattice. Three-level excitation, or some variant, is usually employed.

PARAMAGNETISM is associated with ELECTRON SPIN. The directional quantization of angular momentum leads to the quantization of the energy of the ionic magnetic moments in a steady magnetic field. In general, the ground-state multiplet of these ions is split by the crystal field of the host lattice (Stark effect), and the levels are completely separated by steady magnetic field (Zeeman effect). When the steady magnetic field is applied at an angle to the major symmetry axis of the crystal field, and the resultant Zeeman splitting is comparable with the initial Stark splitting of the levels, the usually forbidden "leap-frog" transitions necessary for 3- or multiple-level excitation become allowed. In crystal fields of low symmetry, "leap-frog" transitions may be allowed at very low or even zero magnetic fields. Clearly, ions having three or more energy levels are wanted, and any processes competing with radiative processes—e.g., the interaction of the "spins" with the lattice—are usually required to be small. Spin-lattice interaction can usually be reduced by cooling the lattice to a low absolute temperature; and indeed most solid-state paramagnetic masers operate at liquid nitrogen (77°K) or liquid helium (4.2°K) temperatures. Some ions and host lattices with which maser action has been achieved are listed in Table 2.

TABLE 2

Ion	Effective Spin	Host Lattice
Cr^{3+}	3/2	Al_2O_3 , alumina (ruby)
Cr^{3+}	3/2	TiO_2 , rutile
Fe^{3+}	5/2	Al_2O_3 , alumina
Fe^{3+}	5/2	TiO_2 , rutile
Gd^{3+}	7/2	$\text{La}(\text{C}_2\text{H}_3\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$ (lanthanum ethylsulfate)

A "spin-spin" interaction process, known as *cross-relaxation* must also be taken into account,

as it may either aid or inhibit maser action. Cross relaxation is dependent on spin concentration, but not on temperature. Consequently, maser action may be achieved at comparatively high temperature (77°K) but not at low temperature (4.2°K) where the considerably longer spin-lattice relaxation time might be expected to give better maser action. Rearrangement of the level populations occurs because of single or multiple quantum transitions between the levels, in which energy is "almost" conserved on the microscopic scale, any differential being exchanged with the energy of the macroscopic spin system (total magnetic moment).

Amplifier Systems. Maser amplifiers may be of either traveling-wave or resonant circuit (cavity) form. Their performances are expressed in terms of a molecular Q -factor, Q_m , defined over unit length for the traveling-wave maser and over the resonator volume for a cavity maser. At the signal frequency f ,

$$Q_m = 2\pi f \cdot \frac{\text{Energy stored in the structure}}{\text{Power emitted by the molecules}} \quad (8)$$

since the Q 's similarly defined for losses are positive.

For a magnetic dipole transition,

$$|Q_m| \propto \delta(N^*p_m^2\eta)^{-1} \quad (9)$$

where δ is the frequency width of the transition at half-intensity, N^* is the *excess* upper level population, p_m is the effective dipole moment for the transition, and η is the ratio of the magnetic energy coupled to the molecules to that stored in the microwave circuit.

Traveling-wave Maser. The active maser material is placed in a waveguide carrying a pure traveling wave. The gain coefficient α_m is defined such that the power gain G for a length l of amplifier is given by

$$G = \exp(2\alpha_m l) \quad (10)$$

It can be shown that

$$\alpha_m = (2\pi f_s) / (|Q_m| v_g)^{-1} \quad (11)$$
